Single-Nucleotide Polymorphism

A. Jeremy Willsey¹ and Montana T. Morris²

¹Department of Psychiatry, UCSF Weill Institute for Neurosciences, University of California, San Francisco, San Francisco, CA, USA

²UCSF Weill Institute for Neurosciences, San Francisco, CA, USA

Synonyms

Single-nucleotide variation; SNP

Definition

A single-nucleotide polymorphism (SNP, pronounced “snip”) is the variation in a single base of DNA that is present in at least 1% of the population (i.e., a common variant). SNPs are a subset of single-nucleotide variants (SNVs); SNVs include both common (SNPs) and rare (<1% frequency in the population) variants of a single base pair. SNP usually refers to a substitution (when a different base pair is present, e.g., ATCCA instead of ATGCA) rather than a single base insertion (e.g., ATGACA) or a single base deletion (e.g., ATGCA). Confusingly, however, the abbreviation “SNP” is also sometimes used to describe insertions or deletions of a few bases of DNA or rare single-nucleotide polymorphisms (which are technically SNVs).

Every human has about three million SNPs (and an additional 150,000 rare SNVs). Therefore, every individual has a unique combination of SNPs (except for identical twins). This diversity means that SNPs can be used to identify a person from a forensic sample (DNA fingerprinting), to identify family relationships, and to examine the ancestral origins of an individual (e.g., North African, Central European, East Asian).

Human SNPs are recorded in several databases, including the NCBI “dbSNP” database (<http://www.ncbi.nlm.nih.gov/projects/SNP/>). Each SNP

Single Case

► Qualitative Versus Quantitative Approaches

has a unique identifier beginning with the letters “rs” (e.g., rs3572840). For many SNPs, ancestry information is given and a small number includes clinical information about known disease associations. There are various other resources that leverage SNPs to provide information about an individual’s traits or ancestry, including private companies that provide individualized sequencing services for customers.

SNPs may be found in coding or noncoding regions of the genome. Some SNPs play roles in regulating the expression of genes (expression quantitative trait loci or eQTLs) and the methylation of DNA (methylation quantitative trait loci or meQTLs). Particular SNPs may increase or decrease risk of a particular disease. Alternatively, a SNP may also act as a marker for a nearby variant that contributes risk or resilience. Therefore, SNPs are commonly used in genetic studies that look for common variants associated with disease, such as genome-wide association studies (GWAS).

To date, GWAS studies of ASD have been limited in their ability to definitively identify SNPs significantly associated with ASD risk. Given that 50% of ASD risk is estimated to be due to common inherited mutations, including SNPs, these negative findings are almost certainly due to a lack of statistical power. Therefore, as cohort sizes (and hence power) increase, significantly associated SNPs are expected to be identified.

Definition

Single-subject research (sometimes referred to as single-case research) refers to a collection of experimental research designs (e.g., multiple

baseline, withdrawal, alternating treatment; see references for list of guides) that can be used to measure the effects of an intervention in individual participants. By manipulating the experimental conditions, each individual serves as their own control, enabling scientists to infer causal relations.

Historical Background

Early examples of single-subject research can be found in research in psychology and physiology conducted in the nineteenth and early twentieth centuries. Scientists such as Fechner, Ebbinghaus, and Pavlov all used individual research subjects and repeated measure over time in their experiments (Barlow et al. 2009). With this focus on the individual and frequent measurement, the researchers could identify variables related to changes in subject performance. These characteristics of frequent measurement, repeated over time at the individual level, are the hallmark of single-subject design because they allow each subject (or *participant* in studies with humans) to serve as their own control. The generality of findings relevant for individuals is then examined with additional subjects to identify fundamental variables responsible for the phenomena under study.

Burrhus Frederick Skinner's research was largely focused on single-subject methodology and resulted in an extensive body of findings related to learning and behavior. Skinner conducted thousands of experiments showing how certain variables resulted in consistent effects on learning and performance (see Ferster and Skinner 1957; Skinner 1938) and, more than any other person, is responsible for the development of the laws of behavior central to fields of the experimental analysis of behavior and applied behavior analysis (ABA; see Baer et al. 1968). Since Skinner and other early scientists pioneered single-subject research, others have continued to use and advocate for the use of single-subject research methodology as the primary way to identify specific variables related to individual's success and lack of progress.

The logic of single-subject design is focused on establishing a predictable trend in behavior, such that if any changes in behavior are noted, they can be attributed to changes made in interventions at the time of the change in behavior. By establishing this predictable trend, or baseline, an individual can serve as his/her own control, eliminating the need for a comparison group or other control procedures. To establish this baseline, single-subject design uses frequent data collection to track performance on target behaviors for a single individual, such as initiating conversation, on-task behavior, or occurrence of inappropriate behaviors. As data are collected, the data can then be summarized in graphical form, which provides a clear illustration of trends in the target behavior over time; trends can be improving, deteriorating, or stable (i.e., no change). Once these trends are established, then changes can be made, if necessary, to improve performance. Following changes, comparisons can be made between pre- and post-change levels in performance.

Current Knowledge

Research studies including individuals with autism spectrum disorders (ASDs and other populations) are often separated into two research paradigms, group-design and single-subject research. Notably, each design is appropriate for some research questions and not others. At times, it has been incorrectly noted that one research methodology is superior to another. This perspective fails to account for the nature of the questions being asked. Broadly speaking, group research is designed to answer what is the average effect of a procedure on a group of individuals. Single-subject research, on the other hand, is designed to ask to what extent will a given procedure result in clear effects observed with each individual. In other words, group-design research asks about the average effect of a treatment, and single-subject research asks about effects at the individual level. In relation to individuals with ASDs, single-subject research has been invaluable because it is sensitive to the wide variety of individual

strengths and challenges experienced by individuals with ASDs and is the only way to identify the key variables and interventions that result in increased success for each individual. In fact, intervention research on children with ASDs and single-subject designs is more frequently used than all other research paradigms (Reichow et al. 2007) and has laid the foundations for the identification of many evidence-based treatments for individuals with ASDs.

Relative to autism research, single-subject design has been invaluable in demonstrating important outcomes for individuals with ASDs and the careful assessment and planning that is necessary to appropriately individualize interventions for each person. In addition to basic and applied research, single-subject design has been central to educational and therapeutic interventions for individuals with ASDs. Single-subject design methodology is also the foundation of effective data-based decision making for individuals in educational and therapeutic settings, where ongoing data collection, progress monitoring, and using those data to identify the need for program revision is essential. The translation of this research paradigm into practice where it can be used to isolate intervention effects at the level of the individual is critical for ensuring that individuals receiving services have effective programs that are helping move them toward optimal outcomes.

Finally, it is important to note that single-subject design is not the same as case study research. Case study research is limited to an account of an individual's performance or experiences over the course of some intervention(s) or a retelling of an account of case(s) from a clinician (e.g., Kanner's original 1943 report of 11 children with early infantile autism could be considered a case study). When used to describe interventions, case study research is not experimental in that it does not allow for clear identification of functional relations between variables (i.e., causal relations), whereas single-subject designs, on the other hand, manipulate experimental conditions such that a functional relation (causal relation), if existing, can be identified.

Singsong

Lisa Edelson-Fries

Department of Psychology, Boston University,
Boston, MA, USA

Neurocognition, Department of Brain Health,
Nestlé Institute for Health Sciences, Lausanne,
Switzerland

Definition

Odd patterns of vocal intonation can be referred to as “singsong,” a term which generally describes a

speech style with a wide pitch range with large rises and falls. It should be noted that this term is somewhat imprecise as it is also occasionally used to describe a very different style of speech with a particularly narrow pitch range, as in a poetry reading, or speech produced to the tune of a preferred song. In all cases, this term is used to indicate that speech has a quality that is different from the typical melodic patterns of conversation. Some individuals with ASD have been noted to have a “singsong” style of speaking, with exaggerated or theatrical-sounding prosodic patterns.

Situations-Options-Choices-Consequences-Strategies-Simulation (SOCCSS) Program

Ernst O. VanBergeijk

Vocational Independence Program, New York Institute of Technology, Central Islip, NY, USA
Threshold Program, Lesley University, Cambridge, MA, USA

Definition

Situations-Options-Choices-Consequences-Strategies-Simulation (SOCCSS) Program is a strategy developed by Jan Roosa according to Myles and Aderson (2001). It is a social decision-making process designed to help students on the autism spectrum and with other disabilities understand social situations. Individuals on the autism spectrum have difficulty in instances where they must understand and act upon the “unwritten rules” of a social situation. It is a step-by-step process by which individuals with ASDs learn to analyze and apply discrete skills in a given situation (Texas Statewide Leadership for Autism 2009). This is a particularly helpful technique because individuals with ASDs have difficulty generalizing skills across environments and situations. SOCCSS can be used analytically as an interpretive tool, or it can be used as an instructional tool to aid in learning how to handle future social situations. Gray’s (1994) *Comic Strip Conversations* has been described as a visual or graphic SOCCSS (Minnesota Para-professional Consortium).

The SOCCSS social skills strategy consists of the six steps that comprise the acronym:

Step 1 Situation: the teacher or therapist helps the individual analyze the problem by answering the five “W’s” (i.e., who, what, when, and why) of the situation.

Step 2 Options: involves brainstorming ways to respond.

Step 3 Consequences: includes a review of the possible consequences of each option generated in the previous step.

Step 4 Choices: consists of reviewing each options-consequences sequence and then prioritizing possible responses. The individual then selects his or her most likely response.

Step 5 Strategy: turns the previous four steps into a plan of action which may include a written script.

Step 6 Simulations: are practice sessions to deal with situation via guided imagery, reading written scripts, role plays, and other forms of behavioral rehearsal (Minnesota Paraprofessional Consortium).

Before the SOCCSS strategy is implemented with an individual with an ASD, he or she should be assessed for his or her abilities across a variety of dimensions. These dimensions include behavioral abilities and characteristics of the person with the ASD. SOCCSS requires some ability to:

- Answer who, what, when, where, and why questions
- Understand a simple cause-and-effect relationship
- Make choices
- Follow multistep directions
- Participate in social interactions
- Problem solve
- Identify or accept a socially appropriate outcome
- Generalize learning (Interactive Collaborative Autism Network)

Characteristics that need to be considered when assessing the appropriateness of SOCCSS or the need to modify the strategy include:

- Literal interpretation of information
- Poor perspective taking
- Inflexibility or a tendency to adhere strictly to a routine
- Difficulty predicting outcomes
- Lack of knowledge about social conventions such as turn-taking
- Lack of understanding of the cause-and-effect relationship of one’s behavior on others
- Difficulty generalizing learning
- Difficulty multichanneling (Lawson 2001), i.e., the ability to respond to more than one stimulus at a time (Interactive Collaborative Network)

Skinner's Verbal Behavior

► Skinnerian Categories of Verbal Behavior

Skinnerian Categories of Verbal Behavior

Elizabeth Schoen Simmons
Department of Psychological Sciences,
University of Connecticut, Storrs, CT, USA

Synonyms

[Skinner's verbal behavior](#); [Verbal behavior](#)

Definition

Skinner's view of language is that verbal behavior is under the control of consequences mediated by other people. He was less interested in the mental structures like knowledge or language competence but rather the functional relationships of the behavior in the environment in which it occurs. The child's response is conditioned by its consequence in a specified situation or what Skinner called the antecedent-behavior-consequence (ABC) structure. For example, a toddler says "bah" and his mother responds, "Sure! Here's the ball." If the child is rewarded for "emitting" a specific behavior (i.e., making a sound), the child will learn to make the sound again under the same circumstances to gain the same reward.

Skinner's categories of verbal behavior include echoic, mand, tact, and intraverbal. According to Skinner's theory, each has a different function and

will be produced under circumstances that elicit that function. An echoic is the repetition of a heard word or phrase for verbal learning and practice, or an imitation. It is elicited by a request for imitation and a reward of the imitation (e.g., caregiver says "apple," child repeats "apple," child then gets to eat a slice of the apple). A mand behavior functions as a request (e.g., child says "car" because he wants access to his toy car) to immediately benefit the speaker. A tact is a label (e.g., child says "duck" because he sees one in a pond). Intraverbals are responses to others' verbal behavior (e.g., responding to questions, taking conversational turns).

Sleep Disorders

► Medical Conditions Associated with Autism

Sleep Disorders and Autism

Susan Calhoun

Psychiatry, Penn State Health and College of Medicine, Hershey, PA, USA

Synonyms

Sleep disturbance; Somnolence

Definition

Sleep disorder is a term used to describe problems with the quality, timing, and amount of sleep that can negatively impact the physical, emotional, behavioral, cognitive, and social development and daytime functioning of youth and cause stress for families. Research has suggested that youth with autism are particularly vulnerable to sleep disorders, with prevalence rates reported as high as 80%. There is also mounting evidence that sleep disorders that are associated with too little sleep or poor sleep quality can worsen certain symptoms associated with autism, such as aggression, somatosensory disturbances, and repetitive behaviors, which can, in turn, make sleeping even more difficult. Furthermore, sleep disorders in youth with autism tend to be more severe, persistent, and resistant to treatment with a higher relapse rate compared to youth with other developmental disorder such as attention deficit hyperactivity disorder and in typically developing youth.

The types of subjective sleep problems most commonly encountered in sleep in youth with autism include irregular sleep-wake patterns; short sleep duration; insomnia symptoms (difficulty falling and staying asleep, early morning awakenings); parasomnias such as sleep waking, night terrors, and bruxism (teeth grinding);

circadian rhythm abnormalities; and sleep complaints associated with medical disorders. Moreover, the prevalence of objectively measured sleep disorders such as obstructive sleep apnea and periodic limb movement disorder are significantly increased in youth with autism.

From a public health standpoint, given the high prevalence and persistence of sleep disorders in youth with autism, all children presenting with autism should be systematically screened for the presence of sleep disturbances and disorders and assessed for any potential co-occurring sleep disorder. If the clinical presentation suggests the risk for any sleep disorder, these youth should be evaluated using appropriate assessment techniques including thorough sleep history and sleep diaries and overnight sleep studies when warranted. Clinicians need to be aware of the impact of sleep disorders in youth with autism and provide targeted evidence-based interventions that include, but are not limited to, behavioral interventions and sleep hygiene techniques, cognitive behavioral therapy for insomnia, chronotherapy, and use of melatonin and prescription medication.

The etiologies of sleep disorders in youth with ASD are likely multifactorial with the interaction of biological mechanisms, psychosocial and environmental influences, and family factors including child-rearing practices that are not conducive to good sleep playing a role. Future research needs to be conducted on the causes of sleep disorders and effectiveness of treatment in youth with autism.

Small-Group Technology-Assisted Instruction Using Socially Assistive Robotics and Virtual Reality

Mohammad Nasser Saadatzi
Department of Electrical and Computer Engineering, University of Louisville, Louisville, KY, USA

Definition

Small-group technology-assisted instruction (SGTAI) is an instructional paradigm, during which a group of students, typically two to four, are instructed by a teacher in a close spatial and temporal proximity. In the SGTAI paradigm, at least one of the students or the teacher is emulated via the usage of virtual characters or robots.

Historical Background

One-to-One Instruction

One-to-one instruction has been long established for instructing individuals with an autism spectrum disorder (ASD). In this format, a teacher uses systematic prompting procedures followed by corrective feedback or reinforcement to instruct chosen target behaviors to a single student. In this format, the instruction is delivered to the target student within a highly structured and well-planned format

and typically isolated from their peers in a contained setting. The efficacy and benefits of this instruction format in terms of behavior development of students with ASD are well-substantiated in the literature and practice. Within this format, the teacher's attention and instruction resources are dedicated to the target student, which reduces distracting stimuli and facilitates skill acquisition. Furthermore, this instructional format may be successfully implemented with minimal prerequisite skills from the student.

Despite the benefits, one-to-one (1:1) instruction consumes teacher's instructional time and, hence, demands copious resources for recruitment and training of qualified instructors. This imposes substantial strain on the educational system as data indicates there is a constant dearth of competent special education teachers (US Department of Education 2014). Besides, this instruction format disregards natural instruction environment and hinders instructional and social integration of such students as they are often separated from their peers during instruction. Relying merely on 1:1 format restricts peer interaction opportunities and may prevent acquisition of social interaction abilities essential for functioning in classroom settings where multi-student instruction is the standard.

Small-Group Instruction

Small-group instruction (SGI) is another instruction format, during which a group of students, typically two to four, are instructed together. Small-group instruction improves efficiency of instruction in terms of teacher's time since multiple students are instructed concurrently. It also more closely resembles inclusive environments and general classroom settings where students are in a close proximity and, thus, prepares an environment with higher chances of peer interaction. Within this arrangement, students may acquire appropriate student-to-student interaction skills and get prepared for functioning in less restrictive settings. Besides, students receive multiple and varied forms of the target behavior, which, in turn, facilitates skill generalization to other people and non-training settings.

Imitational Learning

As a result of exposure to other students' behaviors in the group, SGI provides a context in

which students can learn new responses and skills through imitation of peers. From a behavioral standpoint, imitation, which is a category of observational learning, is defined as an individual's behavior that is contiguous in time and similar to that of a model. For instance, if one shows a thumbs-up in front of a child for the first time and the child emits a similar gesture following the modeled behavior, it would be considered an imitative behavior. An imitative behavior may be strengthened through direct reinforcement.

Vicarious Learning

Another advantage of SGI format is that it provides a context in which students can learn novel skills or refine behaviors by viewing the "consequences" received by their peers for their correct or incorrect responses and behaviors. This type of learning, which is another category of observational learning, is called vicarious learning. Merriam-Webster dictionary defines vicarious as "experienced or felt by watching, hearing about, or reading about someone else rather than by doing something yourself." Vicarious learning involves an individual observing others come in contact with stimulus-response contingencies and, thus, learn without directly receiving consequences. A significant difference between imitational learning and vicarious learning is that the latter may cause behavior suppression as a result of observing non-preferred consequences received by a model due to a behavior. For instance, a child may vicariously learn not to throw a basketball at a peer after he sees negative reactions of other students to another peer doing so. Early studies done by Bandura (1965) demonstrated that children who observed a model received punishment following his aggressive behavior were less likely to match the response of the model and to engage in that kind of behavior. Imitation, on the other hand, can only include an observer's behavior matching that of a model.

SGI provides a context in which a student can vicariously learn new responses by watching teacher's instruction delivered to other students, their responses, and the subsequent teacher's reinforcement or feedback according to their accuracy of response. Therefore, simply by group participation, each student in the group has the opportunity to

acquire skills targeted to other students even when he/she is not directly reinforced for his/her learning.

Despite the aforementioned benefits, for a successful implementation, SGI requires a few prerequisite skills from students. For a successful inclusion and proper progress within an SGI format, students are required to possess certain prerequisite skills, such as contingent turn-taking (without disruptive and aberrant behavior, out of seat behavior, or verbalization) and compliance. Lacking such group-specific skills may adversely affect satisfactory progress of the student and that of his/her peers alike.

Current Knowledge

Computer-Assisted Instruction

Many individuals with ASD find interacting with computers more joyful and comfortable than with humans and feel an affinity with them, suggesting that computer-assisted instruction (CAI) can be an effective intervention method for them (see chapters ► [“Computer-Based Intervention Assistive Technology”](#) and ► [“Computer-Assisted Instruction to Teach Academic Skills”](#)). There have been several studies investigating the use and efficacy and efficiency of CAI for behavioral, academic, and social development of individuals with ASD (Pennington 2010). Although the reported positive gains vary, the overall results are quite favorable. CAI can provide learning environments that are individualized, highly controlled, and structured and can include a variety of modalities, such as text, sound, and images. CAI enhances motivational and attentional factors and increases engaged time and enjoyment in individuals with ASD. CAI also has the potential to reach people on the autism spectrum at a broader scale because of the savings due to automation.

Small-Group Technology-Assisted Instruction

Computer-assisted instruction has been also used in the context of SGI. For instance, Mechling et al. (2007) used PowerPoint slides presented on an interactive electronic whiteboard to instruct recognition of grocery words to students with intellectual disabilities within a small group arrangement. Their instructional procedure

involved a teacher advancing the PowerPoint slides, delivering prompts and directions, reading the target words, and providing reinforcement and feedback to students. This study is perhaps the first to demonstrate the efficacy of CAI in the context of an SGI arrangement.

Saadatzai et al. (2018a) developed an intelligent tutoring system which resembled an SGI arrangement, which featured a virtual character and a humanoid robot. The virtual character, displayed on a desktop screen, simulated a human teacher delivering sight word instruction, with meaningful and contingent gaze behavior, body gestures, and facial expressions. On the other hand, the humanoid robot adopted a peer metaphor and served as an emulated peer for students with ASD. The communication of the virtual teacher (VT) and the robot peer (RP) with students and each other was through synthesized speech and automatic speech recognition, in order to facilitate learning through natural language. In this study, the RP's behavior repertoire (e.g., meaningful body gesture as well as contingent social behavior) was designed to increase students' engagement. The RP demonstrated proper group-specific social behaviors, interacted with the students, and provided a context for the participants to rehearse social skills. The authors demonstrated the efficacy of this tutoring system with three children with ASD. In this study, the VT instructed three types of sight words to student-RP dyads including (i) target words unique to student, (ii) nontarget words unique to the RP, and (iii) target words shared between student and the RP. The results indicated that (i) the students acquired the target words directly instructed to them with 100% accuracy; (ii) they vicariously learned the majority of the nontarget words solely taught to the RP, merely by watching the instruction to the RP; and (iii) they learned the shared target words faster and with fewer errors. The participants demonstrated maintenance of their target words for 8 weeks after the instruction and generalized performance to words written on paper at their homes. They, furthermore, maintained and generalized the nontarget words, which were previously instructed to the RP, with a mean accuracy of 88.89%. In a follow-up study, Saadatzai et al. (2018b) replicated this study with two adults with ASD and reported similar outcomes. These two studies were the first to prepare a small-group

technology-assisted instruction (SGTAI) in an agent-robot-student format and to study the effects of such a learning environment on vicarious learning of nontarget stimuli.

Why SGTAI

National Research Council's Committee on Educational Interventions for Children with ASD recommended that developmentally appropriate SGI instruction should be included in the education of individuals with ASD as group skills are crucial for a student to thrive in inclusive and general classroom settings (National Research Council 2001). Individuals with ASD, however, are often unable to benefit from such instruction arrangements due to their impaired social interaction and communication deficiencies. Furthermore, they often struggle to generalize skills acquired during 1:1 intervention to novel settings and peers. They may become adept at a trained skill but fail to transfer that knowledge to everyday life. This makes development of interventions for these individuals highly challenging. Koegel and Rincover (1974) evaluated the consequences of transferring individuals with ASD from a 1:1 format to an SGI format. In this study, in a 1:1 arrangement, eight students with ASD were first instructed a number of behaviors required for group participation and were then transferred to a group arrangement. The results demonstrated that the students minimally and inconsistently generalized the skills they had acquired in the 1:1 arrangement to the group arrangement, even in a small group comprised of one teacher and two students. Additionally, even prolonged group participation did not seem to produce much change as the students failed to acquire new behaviors during a month-long participation in the group setting. Similarly, Graff, Green, and Libby (1998) conducted a study on the effects of two levels of behavioral intervention. The participant, a 5-year-old child with ASD, received 1:1 intervention for a year, which was changed due to resource limitations. When the student-to-teacher ratio increased, the participant's challenging behavior escalated, while his progress in skill acquisition either decreased or remained stable. In this case, the abrupt change in teacher-to-student ratio seemed to adversely affect his progress in the group arrangement.

Although group instruction can be an effective and efficient instructional arrangement for individuals with ASD, it seems necessary to pay careful attention to how to transit from 1:1 to group settings. Special procedures should be identified and be employed to ensure a smooth shift and avoid abrupt transition for many of these individuals. Furthermore, extra attention must be paid on developing instructional techniques that equip these students with behaviors necessary for multi-student contexts and that prepare them for group participation. Following this rationale, the Division of Early Childhood of the Council for Exceptional Children emphasized on the role and potential of technology to improve access to and participation in general education curriculum and inclusive environments (Stremmel 2005). In this context, SGTAI reflects a novel direction in tutoring systems in which students with ASD can learn and rehearse group-specific social and coping behaviors (such as perspective-taking, reciprocity, and imitational learning) in a controlled environment without negative feedback from and teasing of peers, unnecessary embarrassment, and fear of failure.

It is well-established that resemblance of a training setting to the natural environment (i.e., where behaviors are expected to occur) enhances generalization of skills (Koegel and Rincover 1977; Stokes and Baer 1977). Hence, SGTAI may properly prepare individuals with ASD for group participation by providing a naturalized learning environment that facilitates transition to natural situations. SGTAI provides an educational context where students with ASD learn some target skills (typically academic such as reading), but also certain desirable behaviors are elicited and practiced (e.g., eye contact, gaze following, joint attention, turn-taking, imitation, and attention to other students' responses). SGTAI provides a tightly controlled and reinforcing environment in which students are required to perform group-specific behaviors, facilitating generalization of those behaviors to classroom settings. Although SGTAI should not substitute learning scenarios that more closely resemble natural contexts, it may promote participation in them.

Future Directions

With all the present questions regarding how to include individuals with ASD in regular instructional settings, an enhanced understanding of how these individuals acquire skills in such arrangements is of paramount importance. For future research, the space of possibilities is quite complex. However, the following technologies have immense potential for immediate impact and are significant to explore.

Virtual Reality

Virtual reality learning environments are simulated educational platforms employing computer-generated 3D graphics, which typically incorporate animated characters with instructional roles, referred to as pedagogical agents. Pedagogical agents (PAs) are lifelike virtual characters that interface between the content of an educational environment and students. PAs engage with students through natural language, meaningful body gesture, and contingent facial expressions. In such learning environments, students learn the intended behaviors while interacting with a virtual character exhibiting social and emotional behaviors (such as eye gaze behavior, body gesture, and facial expressions). PAs can be programmed to demonstrate emotional states pertinent to the pedagogical circumstance, such as engagement, confusion, frustration, and curiosity. PAs can utilize eye gaze behavior to simulate joint attentional bids or regulate turn-taking. They can demonstrate head nods/shakes or emotive faces to communicate feedback to the student's responses and actions (Kandalafi et al. 2013; Saadatzi et al. 2017).

In VR learning environments, students can rehearse real-life scenarios through the comfort and safety of a simulated environment, in which physical proximity, sound level, and social interactions are tightly controlled. VR provides a predictable and customizable environment where students can learn and repetitively practice social behaviors through interaction with PAs that require fewer social skills and hence produce less anxiety. A favorable property of PAs is that, depending on the desired purpose, they can serve different educational roles in an SGTAI

environment, such as a simulated teacher or a simulated peer/classmate.

Application of VR for instruction of social and academic skills to students with ASD, particularly in the context of SGTAI, is currently underrepresented, calling for further research to reveal and realize its full potential. To date, most VR tutoring systems for individuals with ASD have been developed as desktop virtual environments (DVEs). DVEs visualize the learning environment on a computer display and utilize conventional devices to receive users' inputs (e.g., keyboard and mouse). As such, DVEs cannot completely surround their users into the synthetic learning environment. On the contrary, immersive virtual environments (IVEs) employ head-mounted displays or VR domes to surround their users in the synthetic environment. It has been suggested that IVEs have the potential to induce higher engagement and can generate an environment with high ecological validity, which are conducive to acquisition of skills and generalization thereof to real world. However, there are a number of concerns associated with the usage of IVEs for individuals with ASD, as they may cause sensory overstimulation, VR-induced symptoms (i.e., cyber-sickness), and irritation due to the head-mounted displays (Wallace et al. 2010). Although previous literature suggests that both desktop and immersive virtual environments are effective tools for instruction of individuals with ASD, their effects on user experience as well as their relative effectiveness are less known and warrant further investigation.

Socially Assistive Robotics

The origination of robotic therapy of ASD goes back to the 1976 through a seminal study conducted by Weir and Emanuel (Weir and Emanuel 1976), where an autistic boy was introduced to a remote-controlled turtle. The researchers investigating robotic intervention for ASD envisage design and construction of robotic systems that can guide these individuals from very simple forms of interaction towards more complicated ones, as those in social human-human interactions, by slowly increasing the system's behavior repertoire as well as its complexity,

duration, frequency, and unpredictability. At first, in a very simple context, the system demonstrates a small set of behavior plans, specifically for those individuals with intense deficiencies. After a while, in a gradual basis, the system features a larger behavior repertoire and plans its behavior, based on an agenda that is therapeutically relevant. The previous literature indicates that robots have the potential to serve as intervention means for individuals with ASD. They can implement multi-modal and embodied social interaction and can closely simulate dynamics of human-human interaction (see chapters ► [Robot-Assisted Cognitive Behavioral Therapy for Young Children with Autism Spectrum Disorders](#)).

Both virtual reality and social robots can create individualized and highly controlled learning experiences that are well reproducible and engaging. However, robots' physical presence and embodiment allow for touch and physical interactions, thereby amplifying their capacity to be employed in certain intervention scenarios. Furthermore, their physicality can aid students with ASD build a rapport and facilitate their joint attention with other entities in an SGTAI environment (i.e., virtual/robot/human teacher and peers). Previous literature suggests that, due to their appealing and salient nature, robots tend to evoke episodes of joint attention in students with ASD, draw their attention, and furnish a playful experience. These potentials may be utilized to steer these individuals' attention to instructional material and enhance their engagement with the SGTAI environment. The salience and novelty of robots may be harnessed as a reinforcer and, thereby, amplify these individuals' investment in the instruction. As individuals with ASD are known to exhibit short attention spans, robots can be employed to enhance students' engagement through their visual appeal and body motion, as well as their interactive behavior. In general, robots are engaging for children with ASD and can offer reduced complexities as compared to human interactions.

Adaptive SGTAI

Since ASD does not occur to the same degree and in the same form in all cases, individuals with ASD are a user group with substantial

heterogeneity. In efforts to justify why human teaching is so effective, the benefits have been attributed to their proficiency in customizing pedagogical strategies and in providing in-depth individualization of content. Against their long-standing promise, however, computerized tutoring systems for individuals with ASD rarely perform such individualization. Future SGTAI systems should adopt an adaptive instruction paradigm by creating and inferring from a dynamic student model, rather than simply using static rules and heuristics. Adaptation to personal learning styles will optimize the learning experience and render the instruction potentially more targeted when an individual is struggling. Future research should deploy and evaluate individualized instruction algorithms in SGTAI, enabling adaptation to individual students' (dis)abilities based on longitudinal observations of interactions with students.

Affect-Sensitive SGTAI

Learning is always accompanied and influenced by a set of affective states. For example, boredom and frustration are negatively correlated with learning gains, whereas confusion and engagement positively influence learning. In a classroom setting, expert human tutors are proficient at detecting the emotional state of students and taking actions accordingly in order to optimize their learning. A few recent tutoring systems, designed for typical students, have incorporated affect responsiveness into their pedagogical strategies. To date, however, little effort has been made to investigate this approach in CAIs developed for individuals with ASD. Given that ASD is associated with differences in emotional experiences and autonomic responses, there is no guarantee that individuals with ASD experience the stimuli in the same way as typical students and that the learning-affect link is the same. It has been suggested that affective and cognitive components are equally influential in educational procedures and that CAI systems with mechanisms for detecting and responding to students' affective states are highly beneficial.

In order for a tutoring system to respond to different affective states of students, it must first be endowed with a means to recognize those

states. Individuals with ASD often have communicative difficulties regarding the expression of affective states which limit traditional auditory and visual approaches in automatic detection of emotions. Future research should investigate what expert therapists observe in individuals with ASD to rate their affective states as well as how they decide upon a course of action in response to that observation.

SGTAI systems should be able to detect students' affective cues but also should intelligently customize their pedagogy accordingly. By considering affective information, SGTAI systems can begin to dynamically tailor their pedagogical strategies not just to the cognitive cues such as number or type of errors made by the student and time taken to fulfill criterion but also to their affective states (e.g., frustration, confusion, interest). As such, an affect-sensitive SGTAI system would not only detect whether students are making mistakes but also whether that is accompanied by curiosity and engagement or by frustration. Therefore, various reactions of the SGTAI system (from the virtual/robot/human teacher and peers) may be created and examined for these different circumstances (e.g., adjusting difficulty level, changing the pedagogical strategy).

Smith v. Robinson (1984) Rights to Attorney Fees for Parents

Silvia Adaes
Quinnipiac University School of Law, Hamden,
CT, USA

Synonyms

[Smith v. Robinson \(1984\)](#)

Definition

This case addressed a parent's entitlement to reimbursement of attorney's fees incurred as a result of legal action against a public school board for discrimination against the special needs of a mentally impaired student. In *Smith v. Robinson*, the Cumberland, Rhode Island, superintendent of schools denied continued funding, by the school committee, of the necessary special programs required by the petitioner, a child who suffers from cerebral palsy and other mental handicaps. The petitioner's parents filed an action in federal district court against the school committee and against various state school officials. The parents brought forth claims for declaratory and

injunctive relief based on state law, specifically the Education of the Handicapped Act (hereinafter "EHA" or the "Act"), on §504 of the Rehabilitation Act of 1973 and, with respect to certain federal constitutional claims, on 42 U.S.C. §1983. Although the district court originally found for the petitioner and awarded attorney's fees, on appeal, the Court of Appeals reversed the lower court's decision on the grounds that the petitioner's action, and subsequent relief granted, fell within the scope of the Act which does not provide for attorney's fees. The Court of Appeals went on to state that notwithstanding the petitioner's federal constitutional claims – which generally allow for the reimbursement of attorney's fees – the relevant decision was within the scope of the EHA and that the Act's omission of attorney's fees does not imply the court's use of federal law in awarding fees. The US Supreme Court thereafter upheld the Court of Appeals' decision.

Conclusion

In *Smith v. Robinson*, although the child's parents prevailed in their claims of discrimination and violation of due process against the school committee in federal court, the US Supreme Court held against reimbursement of attorney's fees for the entire proceedings.

The Supreme Court held that a petitioner availing himself of the EHA and being successful thereunder cannot collect attorney's fees for unsuccessful federal claims simultaneously filed. In addition, the court found that the specific simultaneous claims – §504 of the Rehabilitation Act of 1973 and on 42 U.S.C. §1983 – raised by the petitioners did not, in and of themselves, allow for attorney's fees.

Landmark Clinical, Scientific, and Professional Contributions

Dr. Smith's early research contributed significantly to our understanding that we can improve outcomes for individuals with ASD. His seminal research with Dr. O. Ivar Lovaas provided the first demonstration that children with autism spectrum disorder could be successfully engaged in behavioral interventions and that for some children, intervention resulted in significant gains on standardized assessment outcomes and clinical outcomes. This seminal work not only altered conventional wisdom regarding the possibility of interventions in autism, but it ignited advocacy efforts and provided both hope and a plan for many families. Subsequent to his work on early intensive behavioral interventions (EIBI), Dr. Smith conducted replications studies, assessed long-term outcomes, and specifically evaluated predictors of success in EIBI.

To extend his evaluation of existing interventions, Dr. Smith led and participated in numerous efforts to develop and evaluate novel interventions. Many of these focused on parent-mediated treatments to address concerns such as disruptive behavior and feeding difficulties. This research contributed support to parents' ability to deliver evidence-based interventions to address a variety of challenges and also established that parent-mediated treatment can result in similar or enhanced gains compared to other options, such as medication to address hyperactivity.

More recently, Dr. Smith's work has supported the successful dissemination and implementation of community-based interventions to enhance outcomes for individuals with ASD. His school-based interventions showed that academic and behavioral improvement was possible via interventions delivered in real-world classroom settings and that educators could reliably implement these strategies.

Dr. Smith was actively involved in the development and evaluation of interventions that targeted core difficulties in ASD, in addition to academic and behavioral outcomes. He

participated in multi-site network comparative effectiveness studies evaluating the relative benefits of applied behavior analytical strategies versus social-communication interventions for children with ASD and minimal verbal skills. Dr. Smith also led the development and implementation of a modular intervention to support student with ASD in classrooms that targeted both core and associated features of ASD.

Short Biography

An early friendship with a young man with autism inspired Dr. Smith's application into the doctoral program at the University of California Los Angeles, where in 1983 he was accepted to work with Dr. O. Ivar Lovaas on the UCLA Young Autism Project. With Dr. Lovaas, Dr. Smith engaged in seminal research on behavioral interventions to improve cognitive outcomes for young children with ASD. In 2000, Dr. Smith joined the faculty at the University of Rochester Medical Center, where an interdisciplinary, federally funded autism research center had been recently established under the leadership of Patricia Rodier, PhD. With his collaborators, Dr. Smith was awarded Studies to Advance Autism Research in Treatment (STAART) Center grant, thus beginning a very successful series of funded investigations based in Rochester. Dr. Smith demonstrated research expertise across myriad topics, including longitudinal evaluations of EIBI and assessing predictors of outcomes in EIBI. Acknowledging the significant role that families play in their children's treatment, Dr. Smith collaborated on several, multi-site projects on parent-mediated intervention related to disruptive behavior and feeding challenges. Always mindful of how his research translated into meaningful outcomes for families, Dr. Smith recently focused much of his work on the application of evidence-based interventions in real world settings. Through extensive collaborations with the community and researchers around the country, Dr. Smith led studies on implementation of interventions to support parents, educators, and other school personnel in helping children with autism access appropriate and high-quality

services in home and public school settings – often with an emphasis on families who are traditionally under-represented in research.

Synonyms

7-Dehydrocholesterol reductase deficiency; RSH syndrome; SLO syndrome; SLOS

Short Description or Definition

Smith-Lemli-Opitz syndrome (SLOS) was described by the original authors as “RSH syndrome” based on the first initials of three individuals with SLOS (Smith et al. 1964). New cases were later described and additional characteristics were delineated. SLOS is an autosomal recessive disorder due to inborn error of cholesterol metabolism caused by mutations of the 7-dehydrocholesterol reductase gene (*DHCR7*) (Tint et al. 1994), and the gene was later identified at 11q12-q13 (Fitzky et al. 1998; Wassif et al. 1998; Waterham et al. 1998). In individuals with SLOS enzyme, activity of the protein coded by *DHCR7* is reduced or absent, resulting in insufficient cholesterol synthesis and the accumulation of precursor sterols, 7-dehydrocholesterol (7DHC) and its isomer 8-dehydrocholesterol (8DHC). This deficiency causes extremely variable clinical, physical, and behavioral manifestations: from presenting as a lethal disorder with multiple major congenital anomalies to presenting with minor physical stigmata, as well as behavioral and learning disabilities, autism spectrum disorders, aggression, self-injury, sleep problems, irritability, and attention deficit hyperactivity disorder.

Categorization

Smith-Lemli-Opitz-Syndrome (SLOS) is categorized as an autosomal recessive multiple malformation Mendelian disorder (Kelley 2000; Opitz 1969).

Epidemiology

SLOS has an estimated incidence among individuals of European ancestry in Canada and the USA of 1 in 15,000 to 1 in 60,000 births (Bzdúch et al. 2000; Lowry and Yong 1980; Opitz 1999a; Porter 2000; Ryan et al. 1998; Tint et al. 1994) and a carrier frequency of 1 in 30 to 1 in 50 for the most common SLOS mutant allele in North American populations (Battaile et al. 2001; Nowaczyk and

Waye 2001). In the Asian and African races, SLOS is less common and historically females were diagnosed less frequently due to a lower degree of visible genital anomalies (Porter 2000). In those affected with more severe mutations, there is increased incidence of intrauterine fetal deaths and neonatal deaths. Also, individuals with SLOS who have mild features are often not diagnosed and may come to the attention of clinicians due to the diagnosis of SLOS in a family member.

Individuals with SLOS have a deficiency of 3-beta-hydroxysterol delta-7-reductase activity due to mutation of the 3-beta-hydroxysterol delta-7-reductase gene (*DHCR7*). This enzymatic deficiency impairs the conversion of 7-dehydrocholesterol (7DHC) to cholesterol in the last step of cholesterol biosynthesis via the Kandutsch-Russel biosynthetic pathway. Therefore, total sterol and cholesterol levels are decreased and 7DHC and 8DHC levels are elevated (Porter 2000). In SLOS, the clinical (nonbehavioral) severity of abnormalities correlates with the ratio of the blood level of 7DHC (or the sum 7DHC plus 8DHC) expressed as a fraction of total sterols (total sterols = cholesterol plus 7DHC plus 8DHC) (Kelley and Hennekam 2000). The best biochemical predictor of clinical severity is the plasma cholesterol level, which decreased with increasing clinical severity (Cunniff et al. 1997). Independent of sterol synthesis, absolute blood sterols levels are subject to wide physiological variables, giving a spectrum of variability (Kelley and Hennekam 2000). In one study, approximately 10% of subjects with SLOS had normal cholesterol levels at the time of diagnosis, and the SLOS diagnosis would have been missed without specific quantification of 7DHC (Cunniff et al. 1997).

Natural History, Prognostic Factors, Outcomes

Smith-Lemli-Opitz Syndrome is characterized by major abnormalities of development at birth (Kelley 2000). At 6 weeks of gestation when the heart chambers and cerebral

ventricles are forming, there are disturbances in morphogenesis. Furthermore, at 12 weeks of gestation, more effects are noted during the development of terminal digits (K).

Clinical Expression and Pathophysiology

The clinical manifestations of SLOS are extremely variable and the phenotypic spectrum is broad. At the severe end of the spectrum, SLOS is a lethal disorder with multiple major congenital anomalies, and in mild cases SLOS combines minor physical stigmata with behavioral and learning disabilities. Phenotypic features include developmental delay, abnormal genitalia,

as well as hand and toe abnormalities that may include:

Polydactyly

and toe syndactyly.

Short Thumbs

In mild cases, toe syndactyly may be the only evident physical anomaly (Bukelis et al. 2007).

Hirschsprung disease, sexual ambiguity, or partial sex reversal in 46, XY males and structural defects of the heart, lungs, liver, and kidneys may occur (Kelley 2000). Facial and cranial abnormalities that may occur include hypertelorism, narrow forehead, short nose with upturned nares, prominent nasal bridge, soft cleft palate or bifid uvula, posteriorly rotated and low-set ears, micrognathia, high-arched hard palate, and microcephaly (Kelley and Hennekam 2000). Potential ocular abnormalities include cataracts, underdevelopment of the optic nerve, ptosis epicanthus, unequal palpebral fissures, and convergent strabismus. Other central nervous system (CNS) anomalies include agenesis or hypoplasia of the corpus callosum or cerebellum, increased ventricular size, and decreased size of frontal lobes (Nowaczyk and Tierney 2004). In the more severely affected individuals, there may be lethal brain defects such as holoprosencephaly (seen in about 5%) and incomplete myelination (Jira et al. 2003). Structural abnormalities include callosal abnormalities, a Dandy-Walker variant, an arachnoid cyst, and holoprosencephaly (Caruso et al. 2004). The individuals may have severe language impairment (Kelley 1996; Nwokoro and Mulvihill 1997; Tierney et al. 2000, 2001, Tierney et al. 2001; Tint et al. 1994), with greater receptive than expressive language abilities (Kelley 1996; Tierney et al. 2001). Nwokoro and Mulvihill (1997) described a sleep disturbance and Ryan et al. (1998) studied 23 biochemically confirmed subjects aged 6 months and older and found that 70% had a sleep cycle disturbance that usually did not respond to sedatives. Individuals with SLOS have also been described as “hyperactive” (Elias and Irons 1995; Opitz 1999b), and attention deficit hyperactivity disorder was diagnosed in one child, who was reported to have a positive clinical response to treatment with methylphenidate (Nowaczyk et al. 1998). Abnormal aggression occurred in 35 of 56 subjects (63%) in a repeated manner sometime in the past or present, and 89% of individuals with SLOS had repeated self-injury, 54% had self-biting, 48% had head banging, and 54% had opisthokinesis (a highly characteristic arched backward diving motion of the upper body often resulting in the

child's hitting an object). An additional 7 subjects (13%) did not demonstrate the characteristic opisthokinesis but did arch their neck backward frequently, while 17 (30%) did neither (Tierney et al. 2001). Over half of 17 subjects with SLOS meet Autism Diagnostic Interview (ADI-R) and DSM-IV diagnostic criteria for autism (Tierney et al. 2001), and in another study of 14 SLOS subjects, approximately three-fourths (71–86% depending upon the evaluation method) met the criteria for some variant of ASD, with 50% having met the criteria for autism (Sikora et al. 2006).

The characteristic irritability of SLOS continues throughout life, with aggression reported in both children and adults (Pauli et al. 1997; Ryan et al. 1998). Tierney et al. (2001) found that a group of 30 individuals with SLOS, ages 3.2–32.4 years, had auditory, oral, visual, and tactile processing difficulties (sensory hyper-reactivity/hypersensitivity) that was greater than 2 standard deviations from the mean observed with a group of typical subjects (Dunn and Westman 1997), and had statistically greater difficulties with these behaviors than typical subjects (Dunn and Westman 1997), subjects with attention deficit hyperactivity disorder (Bennett and Dunn 1996), Asperger disorder (W. Dunn, personal communication, 1999), autistic disorder (Kientz and Dunn 1997), and other developmental disorders (Ermer and Dunn 1998). Such injuries frequently present and was found upon interview that 89% of subjects had a history of self-injury at some time and that 68% had self-injury within the prior month including less injurious behaviors such as skin picking, and the Nisonger-CBRF scale demonstrated a self-injury rate of 83% that occurred within the 2 months prior to assessment (Tierney et al. 2001).

Evaluation and Differential Diagnosis

Professional organizations such as the American Academy of Neurology and the Child Neurology Society are recommending screening for biochemical and genetic disorders that are associated with ASDs (Filipek et al. 2000). A clinical diagnosis of SLOS or suspected mild SLOS can be

confirmed by biochemical testing. An elevated plasma 7DHC level relative to the cholesterol level establishes the diagnosis, although 7DHC levels can also be measured in other tissues. Furthermore, although the majority of individuals with SLOS have lower than normal cholesterol levels, approximately 10% of affected individuals diagnosed clinically and biochemically with SLOS have normal total cholesterol levels and only mildly elevated levels of 7DHC (Irons 2007), particularly those who have a milder phenotype or are older (Kelley 1995). Thus, a normal value for plasma cholesterol does not exclude the diagnosis of SLOS. Also, different laboratories may report the 7DHC results in either milligrams per deciliter, micrograms per milliliter, or millimoles per liter (Irons 2007).

Some neuroleptic medications for the treatment of behavioral and psychiatric disorders interfere with the activity of enzyme *DHCR7* and mildly lower the production of cholesterol. This may lead to false-positive test results. Molecular genetic testing and/or fibroblasts testing is needed to clarify the diagnosis in those individuals. More than 120 mutations in SLOS have been described (Correa-Cerro and Porter 2005; Yu and Patel 2005).

Genetic Counseling

Due to the autosomal recessive nature of the disorder, each sibling of an affected individual should be tested as there is a 25% chance that an offspring will be affected, a 50% chance of being an asymptomatic carrier, and a 25% chance of being unaffected and not a carrier (Irons 2007). Carriers are heterozygotes for SLOS and are not at risk of developing the disorder and do not have abnormal cholesterol levels. Biochemical testing of fibroblasts has been used for carrier detection (Shefer et al. 1997), as has molecular carrier testing if the *DHCR7* mutations in the family are known. For evaluation of the affected individual, in addition to biochemical testing, molecular genetic testing is used. Most affected individuals are compound heterozygotes for two different abnormal alleles, with an overall mutation detection rate of 96% (Witsch-Baumgartner et al. 2001). It has been hypothesized that the other

mutations that are not detected on molecular testing are due to mutations that regulate the transcription or function of the gene product (Correa-Cerro and Porter 2005). Biochemical testing or molecular genetic testing can be used for prenatal pregnancies (Irons 2007). Knowing the specific mutation mutations that the parents carry can help to assess for risks in the affected offspring. For pregnancies of carriers in families that may result in SLOS, diagnostic elevation of 7DHC levels may be assessed for in amniotic fluid obtained by amniocentesis (Abuelo et al. 1995; Dallaire et al. 1995; Rossiter et al. 1995) or in tissue obtained from chorionic villus samples (CVS) (Mills et al. 1996; Sharp et al. 1997). In fetuses who have a family history of a mild variant form of SLOS, the 7DHC enzyme deficiency will need to be demonstrated in cultured amniocytes (Irons 2007).

Treatment

Cholesterol is needed not only for myelination, neuroactive steroid synthesis, and cell wall structure in the body but is also needed for modulation of the oxytocin receptor, serotonin receptors, and the G-proteins that are necessary for other neurotransmitter function (Bukelis et al. 2007; Lee and Tierney 2011). The current standard treatment for SLOS is to begin dietary cholesterol supplementation as soon as this condition is diagnosed. Cholesterol is supplied in natural form (egg yolk, cream, liver) or as a purified cholesterol suspension; the dosing for the cholesterol suspension typically is started in the range of 40–50 mg/kg/day up to 150 mg/kg/day for maintenance treatment (Linck et al. 2000). Cholesterol supplementation improves the ratio of cholesterol to total sterols (Elias et al. 1997; Irons et al. 1997; Nwokoro and Mulvihill 1997) and can decrease 7DHC levels (Linck et al. 2000).

Tube feeding is often required in infants and younger children because of feeding difficulties. Medical and surgical management of gastroesophageal reflux may be needed. During severe acute illness (e.g., infections) or following major surgical procedures, patients with SLOS may

develop overt adrenal insufficiency requiring fresh frozen plasma as a source of cholesterol.

Treatment of individuals with SLOS with dietary cholesterol supplementation has resulted in limited clinical effects and benefits. Yet, clinical anecdotal reports and open-label studies with cholesterol treatment in children with SLOS have demonstrated reductions in the number of infections, decreased rashes (Elias et al. 1997), reduced photosensitivity (Azurdia et al. 2001; Elias et al. 1997; Starck et al. 2002), and improved speech articulation (Irons et al. 1997). In a study of six children with SLOS (from birth to 11 years) receiving cholesterol supplementation, Elias et al. (1997) reported that all of the six children had decreased problem behaviors, better tolerance of infection, improvement of gastrointestinal symptoms, as well as the improvement in photosensitivity, rashes, and infections noted above. After cholesterol supplement is begun, individuals had decreased irritability (Elias and Irons 1995; Nwokoro and Mulvihill 1997), a happier affect (Irons et al. 1995; Nwokoro and Mulvihill 1997; Pauli et al. 1997; Opitz 1999b), decreased hyperactivity with improved attention (Elias and Irons 1995), and decreased self-injury. Other behaviors reported to improve with cholesterol supplementation include aggressive behaviors (Nwokoro and Mulvihill 1997; Ryan et al. 1998), temper outbursts, trichotillomania, and tactile defensiveness (Nwokoro and Mulvihill 1997). In order to retrospectively compare the behaviors that occurred before and after cholesterol supplementation began, a Parenting Global Rating Form was completed by the parents of 44 subjects who began cholesterol supplementation after early infancy. The parents of 6 subjects (12%) said that there was no change in behavior following treatment with cholesterol. For the remaining 38 subjects (75%) for whom the parents saw behavioral change after cholesterol treatment was initiated, the mean score was 7.9 ± 1.7 on a scale of 1 (terrible) to 10 (excellent), indicating that they believed that cholesterol supplementation had a very positive effect on average (Tierney et al. 2001). Kelley and Hennekam (2000) also reported that irritability and sleep disorders improved rapidly after initiation of therapy in

contrast to other behavioral issues such as tactile sensitivity which improved over a longer period of time. Furthermore, consistent with what is described by many caretakers, they also reported that behavioral abnormalities return when dietary cholesterol therapy is interrupted. Martin et al. (2001), in a case report, described significant improvement in hyperactivity, aggression, and self-injurious behavior within 48 h of initiating dietary cholesterol therapy.

Elias et al. (1997) reported in six children that all demonstrated improved growth and more rapid progress in development after cholesterol supplementation was begun, with increased pubertal progression in the older subjects. In contrast, however, in a longitudinal study of cognitive, motor, and adaptive developmental progress in 14 youths with SLOS receiving cholesterol supplementation, Sikora et al. revealed that despite dietary cholesterol supplementation, developmental quotients did not improve over time (Sikora et al. 2004). Similarly, in a double-blinded placebo-controlled, crossover trial in ten individuals with SLOS, Tierney et al. (2010) found no short-term behavioral effects of dietary cholesterol supplementation. The disparities in clinical improvements demonstrated by these studies may be related to the absence of a direct cholesterol transport mechanism across the blood-brain barrier (Lee and Tierney 2011). It is possible that supplementation with cholesterol beginning in infancy or early childhood may improve cognitive outcomes in SLOS patients. But, to date, no positive effect of cholesterol supplementation on cognitive development has been found in a controlled prospective study. Although Sikora et al. (2004) found that the developmental status of SLOS did not improve over time with cholesterol supplementation, it is possible that supplementation with cholesterol beginning in infancy or early childhood may improve cognitive outcomes in individuals with SLOS.

Dietary cholesterol therapy may impact the development of or presentation of autistic features. Individuals with SLOS treated with cholesterol have been reported to be more sociable, including initiating hugs and being more interactive (Irons et al. 1995; Ryan et al. 1998). Of

subjects with SLOS who began cholesterol supplementation before the age of 5.0 years (9/17), 22% met the criteria for autism at ages 4.0–5.0 years while on supplementation, whereas, of the 8 subjects not supplemented with cholesterol before age 5.0 years, 88% met the criteria for autism at ages 4.0–5.0 years while not on supplementation (Tierney et al. 2001). Although these findings are retrospective and in a small population, they suggest that cholesterol supplementation might have decreased the severity ASD symptoms that would have occurred. Furthermore, no side effects have been reported with cholesterol treatment, which has been in use for about 15 years, serum cholesterol levels are rarely normalized, and elevated 7DHC levels persist. There is data that suggests 7DHC has some toxic effects in that 7DHC increases the degradation of HMG CoA reductase (resulting in lower sterol levels) (Fitzky et al. 2001) and that 7DHC impairs intracellular cholesterol transport (Wassif et al. 2002). O'Brien et al. (2002) suggested in a rat model that correction of the SLOS CNS biochemical defect is associated with return of a normal eye-blink response.

Multiple lines of evidence suggest that statins, a class of medications used to lower cholesterol in those with abnormally high levels, may improve DHCR7 activity, resulting in increased cholesterol levels in individuals with mild DHCR7 deficiency (Jira et al. 2000), in human fibroblasts from mildly affected individuals (Wassif et al. 2005), and in an SLOS mouse model (Correa-Cerro et al. 2006). The mechanism by which statins may increase plasma cholesterol is hypothesized to result from increased expression of a *DHCR7* allele that encodes a mutant enzyme with residual enzymatic function and is supported by in vitro experiments using SLOS fibroblasts (Wassif et al. 2005).

Mildly to moderately raised levels of 7DHC have been found in three psychiatric patients without SLOS who were treated with haloperidol (Nowaczyk and Tierney 2004), with 7DHC levels directly proportional to the dose of haloperidol. 7DHC levels decreased to normal upon haloperidol discontinuation, although it is unknown if an increase in the 7DHC level would have a

beneficial or a deleterious effect. However, the benefits of these medications for behavioral treatment may outweigh the potential risks of lowering cholesterol synthesis. If the behavioral and learning deficits reported in SLOS are related to alterations in sterol composition, rather than fixed developmental defects, then therapeutic interventions designed to alter brain sterol composition may be effective in improving behavioral symptoms (Aneja and Tierney 2008).

Social Behaviors and Social Impairment

Cheryl Dissanayake

Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia

Definition

Social behaviors encompass all behaviors used to interact and communicate with other people. These comprise behaviors as simple as looking

at another and smiling at them to more complex behaviors such as entering into a crowded room with a group of strangers and beginning to interact with them. Many of these behaviors, from the most simple to complex, are challenging for people with an autism spectrum disorder (ASD). Impairments in the development of social behavior, or social impairments, lie at the heart of autism.

Historical Background

Impairments in social behaviors have been noted from Leo Kanner's (1943) original observations, on which he based his first detailed account of 11 cases of autism. He observed the failure of these children to interact with other people in the usual way, with many preferring to be alone. He wrote about their failure to look at other people and to even notice their presence/absence, such that "Comings and goings, even of the mother, did not seem to register" and "The father or mother or both may have been away for an hour or a month; at their homecoming, there is no indication that the child has been even aware of their absence." Impairments in social interaction and behavior have continued to be considered at the heart of autism, with the various iterations of the DSM (from 1980 onward) including persistent difficulties in social interaction as one of the core diagnostic features.

Current Knowledge

The lack of social reciprocity, considered a core underlying feature of ASDs, is evident from the period of infancy (Barbaro and Dissanayake 2009) and persists throughout development and into adulthood (Taylor and Seltzer 2010; Howlin et al. 2013). Early forms of social impairment are evident in the failure to engage in reciprocal face interactions with the caregiver(s) comprising behaviors such as eye gaze, affect sharing, and bouts of mutual facial and gestural imitation. These early dyadic behaviors culminate in social

routines like peek-a-boo-type games in typical development, which are mutually rewarding for both social partners.

The early deficits in dyadic interactions in autism during infancy lead to concomitant difficulties in triadic interactions, such as engaging in joint attention (shared gaze/affect with a social partner and an object/event of mutual interest) and social referencing. The use of social gestures, such as pointing and waving, typical in prelinguistic children, is also infrequent. Impairments in empathic responding and the early developing positive social behaviors like helping and sharing (collaborative prosocial behaviors) ensue. However, despite these early developing difficulties in social engagement and responding, it is important to note that children with autism develop attachments to their caregivers, which are functionally and qualitatively similar to those of their non-autistic peers (Chandler and Dissanayake 2014).

In early childhood, there is little initiation of social interactions with other people, which becomes clearly evident during the preschool years, in interacting with peers. Children with an ASD are usually found on the periphery of social activity with little social play evident (Macintosh and Dissanayake 2006). Solitary play is the norm unless the child is directly engaged in an interaction with a mature play partner. As a result, peer relationships are limited and, when evident, center around the more narrow interests of the children with an ASD. Thus, friendships are infrequent among these children, leading to missed opportunities to use and practice their social behaviors and skills. The capacity to form and maintain relationships with peers is a crucial developmental task for children, and impairment in this ability is still recognized as a core feature of ASDs (DSM 5, 2013).

The development of perspective-taking skills, critical to the development of social relationships, is compromised in autism. Turn taking in interactions is difficult. Taking another's affective and/or cognitive perspective is crucial to understanding other people as well as understanding the self in relation to others. Indeed, the development of selfhood in autism is atypical

which lies at the core of their social-cognitive difficulties (Hobson 1990; Lombardo et al. 2010). The development of social understanding and social responsiveness is deeply intertwined, and each is compromised in autism. It is important to note that it is not just a lack of social behaviors but also knowledge of how and when to use what social behavior and skills have been acquired that leads to the marked social impairment in autism.

The direct consequence of the social interaction difficulties, particularly found among more able children and adolescents with an ASD, is social isolation and peer rejection, leading to poor social support and reported loneliness (Bauminger et al. 2003). Often, these higher-functioning individuals report a desire for friendships but lack the necessary social skills to go about establishing them. The commonly reported mood (depression and anxiety) problems in these individuals, especially common during adolescence and adulthood (Hedley et al. 2017), are likely to be exacerbated by their social difficulties.

Future Directions

Given the centrality of social impairment in ASDs, the teaching of social behaviors and skills comprises an important component in any intervention program, regardless of age and ability level (White et al. 2007). In addition to teaching social behaviors and skills, a key component of any intervention program is to motivate affected individuals to interact socially with others. The development of social competence relies on this.

More research is sorely needed on the efficacy/effectiveness of intervention programs designed to enhance the social behaviors and skills of infants, children, adolescents, and adults with an ASD. These lifelong developmental disorders are likely to demand developmentally appropriate social intervention treatments that change to accommodate the particular life stage. As with all interventions, treatment efficacy will be enhanced if these begin at the earliest possible time in development.

Social Camouflaging in Adults with ASD

Laura Hull and William Mandy

Research Department of Clinical, Educational and Health Psychology, University College London, London, UK

Definition

A description of the construct of camouflaging (minimizing the appearance of autistic characteristics during social interactions) and current literature.

Historical Background

The earliest known record of the concept of camouflaging in the academic literature comes from the seminal work of Lorna Wing, who described autistic girls without intellectual disability, who appeared to have better social and communication abilities than comparable males, and so were likely to be missed in clinical assessments (Wing 1981a). As part of this “camouflaging hypothesis,” she also described examples of both males and females learning social rules, which might result in apparently typical social behavior despite underlying difficulties (Wing 1981b). However, the concept of some autistic individuals having superficially improved social skills was not considered in depth by academics for many years afterward.

Meanwhile, both clinicians and autistic individuals themselves described case studies of individuals learning to “pretend to be normal” (Holliday Willey 2015). These accounts often focused on females in particular, and suggested that using specific, learned strategies might mask the appearance of social difficulties in autistic females, and thus make it harder to identify their autism (Kopp and Gillberg 1992). Other clinicians identified or suggested specific camouflaging behaviors, such as suppressing repetitive hand movements, giving scripted answers while chatting, or staying close to others without actually

interacting (Gould and Ashton-Smith 2011; Kreiser and White 2014; Lai and Baron-Cohen 2015; Mandy and Tchanturia 2015), although none of these were tested in large-scale, high-quality studies. The implied consequence of these behaviors was that they made identification of difficulties harder by teachers or clinicians, even if the individual themselves or their parents may be aware of difficulties (Mandy et al. 2012).

Most of these studies focused on camouflaging in females, as part of the consideration of the female autism phenotype, or a female-specific behavioral expression of autism (Lai et al. 2011). It was suggested that autistic females might have more social reinforcements or expectations to adapt their behaviors depending on the social environment (Kreiser and White 2014). A complementary approach at the same time suggested that there may be genetic protective effects which allowed females to compensate for some autistic difficulties, with the possibility of not requiring an autism diagnosis (Dworzynski et al. 2012).

The first studies to explicitly examine the concept of camouflaging were qualitative, and mostly based around interviews with autistic girls, women, and their parents. More strategies were identified, such as mimicking peers’ social behaviors (Cridland et al. 2014), or developing coping strategies to attempt to deal with the exhausting social world (Tierney et al. 2016). Some autistic women suggested that their camouflaging or masking strategies made it harder for them to receive a diagnosis, as clinicians did not understand they were masking some of their symptoms (Bargiela et al. 2016; Milner et al. 2019). These studies all supported the idea that camouflaging may be a mostly female behavior, with gendered consequences for diagnosis and outcomes.

Lai and colleagues (2017) were some of the first to operationalize camouflaging, using a so-called “discrepancy” approach. Camouflaging can be measured as the discrepancy between an individual’s internal autistic status, and their external autistic presentation. By measuring camouflaging in this way in a mixed gender adult sample, Lai and colleagues demonstrated that camouflaging can occur in both males and

females and that there is substantial individual variation in the extent of camouflaging. However, camouflaging is on average greater (discrepancy scores were higher) in autistic adult females than males. A complementary measurement approach, used by Hull et al. (2017), operationalized camouflaging based on the self-reported experiences of autistic adults, known as an observational/reflective approach. In this large qualitative study, the vast majority of autistic adult males, females, and individuals of non-binary gender described using camouflaging strategies at some point in their lives. This analysis produced a conceptual model of camouflaging, including its motivations, strategies, and consequences, which has informed subsequent research.

Current Knowledge

Camouflaging is conceptualized as the process of “hiding behaviour that might be viewed as socially unacceptable or artificially ‘performing’ social behaviour deemed to be more neurotypical” (Lai et al. 2017). It can be deliberately learned, such as gradually reducing stimming behaviors, or automatically performed, for instance, mimicry of others’ speech patterns (Hull et al. 2017). As a relatively new topic of research interest, current knowledge is developing rapidly and the specific characteristics of camouflaging are still being determined.

Motivations for camouflaging include short-term or functional aims, such as performing well in a job interview or avoiding bullying from others, in addition to longer-term and relational aims, such as developing friendships (Cage and Troxell-Whitman 2019; Hull et al. 2017). It is still unclear to what extent these aims are achieved, and which abilities may be needed for successful camouflaging. However, individuals who camouflage deliberately may reflect on their camouflaging strategies in order to better achieve their aims (Hull et al. 2017), while those who are not aware of their use of camouflaging strategies may not be able to manipulate their behaviors.

Strategies for camouflaging have been identified or reported through a variety of mechanisms. Studies following the discrepancy approach described above have measured the extent of camouflaging as the discrepancy between mentalizing abilities and ADOS score (Lai et al. 2017, 2018; Schuck et al. 2019), between theory of mind and ADOS score (Livingston et al. 2018), and between parent-reported autistic traits and various behaviors associated with autism (Boorse et al. 2019; Parish-Morris et al. 2017; Ratto et al. 2018; Rynkiewicz et al. 2016). While this enables comparison of camouflaging between groups, it is harder to identify specific instances of camouflaging in real life.

Studies following an observational/reflective approach have identified specific camouflaging strategies, either through behavioral observation (Dean et al. 2017) or through self-reported camouflaging (Cage and Troxell-Whitman 2019; Hull et al. 2018). Examples of these strategies include playing next to, but not with, other children; developing a script for social situations; and learning social behaviors from others. Camouflaging can be measured using the psychometrically validated self-report Camouflaging Autistic Traits Questionnaire (CAT-Q) in adults.

Although there may be beneficial aims associated with camouflaging, most studies report negative consequences of camouflaging. Autistic individuals have self-reported experiencing exhaustion, mental health difficulties such as anxiety or loneliness, and feeling inauthentic (Hull et al. 2017; Milner et al. 2019; Tierney et al. 2016; Tint and Weiss 2018). Quantitative measures of camouflaging have shown positive associations with depression, anxiety, and suicidal ideation (Cassidy et al. 2018; Hull et al. 2018; Lai et al. 2017). In addition, camouflaging has been proposed as a factor preventing autistic girls and women in particular from receiving an accurate and timely diagnosis (Bargiela et al. 2016; Hull et al. 2017).

Researchers have recently begun to examine gender differences in autistic camouflaging. Discrepancy-based studies have generally found that females have a higher discrepancy between internal and external autistic experiences,

resulting in greater internal experience of autistic characteristics, but lesser external presentation of autism compared to males (Lai et al. 2017; Ratto et al. 2018). However, the proportion of autistic adult males and females who report having camouflaged does not appear to differ; the vast majority of autistic adults of all genders report having camouflaged at some point in their lives (Cage et al. 2018; Cassidy et al. 2018; Hull et al. 2017). Research using self-report measures reveals mixed findings so far (Cage and Troxell-Whitman 2019; Cassidy et al. 2018; Hull et al. 2019).

Future Directions

Although the field of camouflaging research has expanded dramatically since 2015, this is still a very new area with many future directions for research. All research has so far taken place in Western cultures, therefore estimates of the prevalence, consequences, and potential gender differences in camouflaging in other cultures need to be identified. Research has also been limited to autistic individuals without intellectual disability; although it has generally been assumed that individuals with intellectual disability or minimal language do not camouflage, this needs to be actively tested.

Camouflaging is also likely to vary across situations, and across developmental stages, within individuals. Longitudinal studies are necessary to identify when and how camouflaging first develops; most research has focused on adults but some studies have identified camouflaging in adolescents and younger children. Earlier identification of camouflaging can help researchers understand how camouflaging develops across time, and how consequences for mental health arise and, potentially, can be addressed.

Larger scale samples using a variety of methods are needed to systematically answer questions concerning gender differences in autism; once these studies are available, meta-analytic techniques will be useful to integrate multiple different studies to give a more definitive answer. Although some research into camouflaging has included non-binary people (Cage and

Troxell-Whitman 2019; Hull et al. 2017, 2019), there are still many gaps in our understanding of camouflaging by transgender and non-binary individuals, and how gender identity interacts with autistic identity.

Future directions for clinical research should focus on implications for diagnosis and interventions. Longitudinal studies identifying participants pre-assessment can help us understand the role camouflaging plays in the diagnostic process, particularly for females. Many social skill interventions, particularly those advocated for younger children, promote social strategies similar to camouflaging, such as forced eye contact. It is still unclear to what extent camouflaging overlaps with these strategies, but the mental health problems associated with camouflaging suggest that more research is needed to evaluate the longer-term implications of deliberately learned social strategies.

status undoubtedly has profound impacts on the diagnosis, severity, and treatment of autism, in which individuals from lower social classes tend to have later diagnoses, harsher symptoms, and less access to psychological and pharmacological treatments. As a result, social class is an important factor to consider when studying autism, especially when studying the efficacy of interventions.

Social Class and Autism

James Hyun Lee
Mayo Clinic School of Medicine, Rochester,
MN, USA

Definition

Social class, also deemed socioeconomic status, is a categorization of a group or individual within an established hierarchical social structure based on factors such as education, income, occupation, financial stability, and location. In statistical analyses, social class can be used as an independent variable when analyzing large populations and is often reduced to a select few variables (e.g., net income, gross income, parental education, property value, nature of labor) for statistical purposes. Social class often plays a significant role in the etiology of a disease, and lower socioeconomic status tends to correlate with higher rates of incidence and severity. Autism spectrum disorder (ASD) has a more complex intersection with social class than most other diseases, likely attributed to its large variance of symptoms between different patients and the fact that mental illness is more difficult to track and study than physical.

There is no official consensus within the field concerning the prevalence of ASD in one social class over another, as multiple studies and statistical analyses have yielded contradictory results from their various populations. However, socioeconomic

Historical Background

Social class became an established concern surrounding autism when it was first introduced by Leo Kanner's hallmark study (1943) of 11 children exhibiting antisocial symptoms. Each one of these children came from a wealthy family with highly educated parents, and the public eye speculated that autism may be a "rich man's disease." Throughout the following decades, especially the 1960s, multiple reviews of different populations in America and Europe continued the narrative that autism diagnoses were more prevalent in wealthy and middle-class families than those of the lower classes.

In the following two decades, the narrative began to shift, where studies heralded results finding no differences in autism rates between the socioeconomic classes. This literature primarily emerged from the United States, which had varied healthcare policies across different states. More recently, landmark studies from Denmark (Larsson et al. 2005) and Sweden (Rai et al. 2012) explored the effects of a universal healthcare system on the prevalence of ASD. Universal healthcare bridges some (but not all) of the inequities that lower social classes face by providing equal access to healthcare regardless of socioeconomic position. By using a variety of variables that measured socioeconomic status, Larsson et al. (2005) concluded that social class played "little or no role in the etiology of autism in Denmark," whereas the equivalent study in Sweden (Rai et al. 2012) concluded that more children in lower social classes are diagnosed with ASD than those in higher classes.

To this day, there is still no consensus among psychologists and sociologists about ASD's prevalence in certain social classes over others and how it interacts with the disorder's etiology. This phenomenon is due to the fact that across separate studies and analyses, researchers used different methods when selecting eligible patients, categorizing the socioeconomic statuses of families, analyzing the data with various statistical tests, and interpreting those statistics in those publications. Further standardized research is required to obtain a clearer vision surrounding how social class can affect the onset of autism.

Current Knowledge

Social Class and ASD Diagnosis

There is an understanding within the field that families from lower social classes are proportionally given fewer ASD diagnoses than higher-class families due to a variety of factors. The most significant factor is that families from lower social classes in systems that do not provide universal healthcare often find themselves in positions where they cannot afford medical appointments. As a result, they do not address pressing or concerning health necessities because they fear the enormous costs. Proportionally, fewer individuals from low-income backgrounds actively seek out healthcare, and they are widely less confident that they could obtain healthcare if necessary (Kirby 2008). These individuals often consider free clinics or clinics for the uninsured as their sole accessible source of healthcare, and these clinics operate on lower budgets, fewer resources (i.e., language interpreters, appropriate legal/social services, specialized care), and fewer appropriately educated staff. Additionally, the primary function of these free services are not dedicated to psychological disorders, so diagnoses for ASD would be secondary to more noticeable medical concerns. Similar lack of access is seen with rural populations that live hours away from a healthcare professional and even further from someone with psychology expertise.

Another factor in the socioeconomic inequality for ASD diagnoses is expressed by the heavy stigma against mental health. For lower classes, psychological health is perceived as a luxury for those who can afford it (Corrigan 2004). These perceptions are further accentuated in non-Western populations, whose cultural identities accentuate weakness if someone is in need of mental health services. Even if this stigma did not exist, education surrounding autism is sparse, and receiving a diagnosis for ASD typically requires active, educated efforts from a patient's family. Parents of children from lower socioeconomic backgrounds are likely to be less educated, more likely to ingrain stigma around ASD, and less likely to believe that their child has a treatable disorder.

Yet another factor is implicit biases found within experts in child psychiatry, who may misread symptoms or dismiss patients due to their lower socioeconomic status. Child psychiatrists were more likely to give an ASD diagnosis to a child from a higher class, whereas they were more hesitant to give the same diagnosis to a child from a lower class with identical symptoms, whom they were more likely to diagnose with cultural deprivation or attentional deficits (Cuccaro et al. 1996). These implicit biases surrounding lower-class populations and resultant misdiagnoses erect barriers for poorer families to efficient treatments for ASD, causing further healthcare disparities between the different classes.

Social Class, ASD Severity, and Well-Being

A common priority throughout the field surrounding autism is early diagnosis for children. Later diagnoses lead to later interventions, which can progress to harsher symptoms and greater difficulty when attempting to integrate into society. Late diagnoses have also been shown to correlate with higher rates of nonverbal cases and greater antisocial tendencies post-adolescence. Socioeconomic status was a stronger predictor for the age of autism diagnosis than the severity of the symptoms when diagnosed (Fountain et al. 2011), and children with parents of higher education were

often diagnosed earlier than those of parents with lower education.

Due to the late diagnosis and resultant lack of preventative healthcare, children of parents from lower social classes often face less effective interventions resulting in harsher symptoms that are difficult to rectify in adulthood. Also, ASD frequently snowballs with various other mental disorders such as depression, anxiety, or attentional deficits (Liss et al. 2008), as well as physical diseases like obesity and malnutrition. The creation of an intervention that addresses not only autism but also a mix of mood, attentional, and physical complications may not be possible in many patients, especially with the extremely severe cases found in children who are diagnosed late. Early diagnosis is inconsequential if the resulting interventions are ineffective, and families from a lower social class are disadvantaged both in terms of age of diagnosis and intervention efficacy. (For focus on the latter, see section “[Social Class and ASD Treatment: Pharmaceutical and Behavioral.](#)”)

Accompanying low socioeconomic status are other trends that affect the severity of the disorder. For example, lower amounts of family involvement correlate with greater severity of the disorder (Dunlap 1999). Parents of lower-class families tend to work long hours, especially single parents with multiple children. As a result, the lack of parent involvement in a child’s life can increase the severity of his/her symptoms, which can also harm the development of self-determination and well-being of the adolescent (Dunlap 1999).

ASD also augments the severity of ailments in other, more specialized realms of health, a phenomenon exemplified by dental care. Dentistry is inherently invasive and requires a stationary patient, so children with autism are difficult patients to treat. Though research continues in order to make the dentist’s office a more accommodating place for individuals with ASD (Marshall et al. 2007), many of these patients, especially those with parents of low education, completely neglect dentistry. Similar “luxury” fields of health like optometry, physical therapy, and nutrition counseling are likewise

neglected, though they may be necessary for an improved quality of life for the patient. Many guardians who come from uneducated backgrounds fear bringing an individual with ASD into these offices given the stigma of the disorder. Even if they overcome this fear, locating educated, willing physicians and counselors who can administer these services to patients with ASD may also be difficult given the limited resources of a less educated guardian.

Ultimately, the diagnosis of ASD is a catalyst for important changes in a patient’s life. However, without effective interventions that address both mental and physical diseases that accompany the disorder and basic support systems like a stable family and home, ASD can increase in severity and actively compound with other health deficiencies to harm a child’s well-being. Families from a lower socioeconomic status lack the education, resources, and time to provide their child with these various support and treatment systems, resulting in disproportionately more severe cases attributed to low-income, less-educated families.

Social Class and ASD Treatment: Pharmaceutical and Behavioral

The treatment of autism can be expensive and cause significant financial losses as patients undergo various interventions to treat the disorder. Families from lower classes tend to be barred from empirically tested treatments due to high costs and inconveniences. Given the difficulties of transportation, location, and finding sufficient time, in addition to certain stigmas and unconscious bias from healthcare providers against poorer individuals, families from lower classes are at a disadvantage when it comes to actively treating an individual’s autism.

Specifically, some pharmaceuticals for behavioral disorders have been empirically tested to alleviate some of ASD’s symptoms (Ratey et al. 1987), and the costs of these pharmacological interventions are often too high for families of lower classes. Although these pharmaceuticals do not address the specific social disabilities of ASD, they can greatly improve the quality of life for both the child and surrounding family members. However, for families from a lower social class, issues of cost immediately come to mind as

they consider these kinds of treatments. Pharmacological interventions require not only the drugs themselves but also consistent appointments with child psychiatrists and pharmacists. Many families from lower classes simply cannot keep up with these regular expenses and forfeit their child's treatment before completing the regimen. Though paid trial sessions for experimental interventions could waive some of the accompanying costs, the field is bioethically critical of allowing populations from lower classes to take the brunt of the trauma from untested procedures.

On the other side of treatment is active behavioral therapy, which consistently demonstrates its efficacy in improving the symptoms of ASD (Reaven et al. 2012). Families of lower social class run into identical problems as those in pharmacological interventions (i.e., lack of transport, low availability of centers/clinics, significant debt from therapy sessions). These regular expenses immediately make individualized therapy inaccessible to most families in lower classes. Though specific insurance measures have been placed throughout Western countries to allow families from low-income backgrounds to receive healthcare (e.g., free universal healthcare in Europe, Medicaid in the United States), psychotherapy is still viewed as a luxury (Kataoka et al. 2002). Additionally, many private insurance companies do not make provisions for mental health in their coverage, so families from both lower and middle classes cannot afford psychiatric therapy for their child with ASD.

Aside from traditional therapy sessions, innovative programs like Ramapo in New York, Chapel Haven in Connecticut, and Camp Talisman in North Carolina are similarly financially inaccessible for low-income patients. These programs use camp or dormitory settings to promote teamwork and social interactions with others. Need-based scholarships are scarce within these programs, and the vast majority of the students who attend these programs are from wealthy socioeconomic backgrounds who can afford the cost of transitioning into a social world.

Combinations of these various treatments – pharmacological, behavioral, and nontraditional – can become extremely expensive, and families

who cannot initially afford such programs could develop severe debt. Unlike college educations, a child with ASD is not likely to return on these investments with a consistent job, so these interventions are administered with little chance of recouping finances. As a result, families from different socioeconomic backgrounds address the future of their children with ASD differently.

It is possible for therapy to continue through adulthood, and some individuals with ASD will be able to integrate themselves into a society with regular assistance from a mental health professional. However, many individuals from lower socioeconomic statuses will not improve, especially given the disadvantageous late diagnoses and lower-quality interventions that accompany lower social classes, and families must continue expensive care for the afflicted member. With resources for adults with ASD (e.g., care homes) costing multiple thousands of dollars a year (Carbone et al. 2010), ASD can consume the lives of families from lower social classes even through an afflicted individual's adulthood.

Future Directions

To better understand the intersection of ASD and social class, the field must conduct further research to understand how social class can affect the etiology of autism. In these future studies, standardization of eligible patients, variables calculated, and how these variables are interpreted is critical in order to better understand how socioeconomic status contributes to autism's symptoms in individuals.

Additionally, there is a consensus in the field that increasing mental health awareness in educational systems worldwide is absolutely critical, especially in low-income neighborhoods. Standardized earlier interventions for autism with routine screenings in all schools would allow for less prevalence of severe ASD in adulthood. Also, this kind of education will foster a culture against bullying toward those with mental disorders in schools (Van Roekel et al. 2010) and increase the quality of afflicted children's lives. As a result, further studies should explore the most effective

ways to raise awareness of ASD for parents of children, expert psychologists, healthcare professionals, teachers, and classmates in order to address mental health as a whole, especially in impoverished areas.

Social Cognition

Nirit Bauminger-Zviely
School of Education, Bar-Illan University,
Ramat-Gan, Israel

Definition

The mental processes in which individuals are involved with when making sense of the social world, including the understanding of self, others, and the interplay between self and others, are what is called social cognition (Lewis 1999; Beer and Ochsner 2006). Social cognition broadly includes the cognitive processes that enables spontaneous decoding and encoding (provide correct interpretation) of verbal and nonverbal social and emotional cues, the ability to recognize central and peripheral social and emotional information, the knowledge of different social behaviors and their consequences in diverse social tasks (e.g., social

knowledge and understanding), and the ability to make an adequate attribution about another person's mental state (i.e., "theory of mind" abilities, Perner and Wimmer 1985), as well as about the self (Crick and Dodge 1994; Lewis 1999). Social cognition, thus, is including information processing about all people, including the self, and about the norms and procedures of the social world. The knowledge about social norms and procedures is both declarative and procedural. By large, declarative knowledge is what the individual knows about social concepts, scripts, relations, and phenomena, and procedural knowledge is the knowledge of rules, skills, and strategies that enables the use of declarative knowledge in order to react or respond efficiently in diverse social situations.

Definition

Social impairments are among the most recognizable features of autism spectrum disorder (ASD), presenting early in infancy and persisting through the lifespan. Reduced affect recognition and difficulty in predicting thoughts and feelings in others are critical features of ASD – particularly in verbal, cognitively able individuals. Advances in social neuroscience led to identification of key neural networks underlying social cognition with consistent findings of ASD-specific neural responses in regions associated with perception of biological motion, face and emotion recognition, and perspective taking.

The foundation of advanced social cognitive skills such as perspective taking and empathy lie in early social communication behaviors such as imitation and joint attention. Recently, several efficacious interventions have been established for critical early social communication behaviors in young children with ASD. Targeted behavioral interventions for social cognition are emerging and typically utilize social group formats. Results from randomized, comparative trials of social cognitive skills groups suggest moderate, short-term effects on informant reports of social behavior and quality of life. However, changes on neuropsychological measures of social cognition are less consistent and with small effects. Pilot, wait-list controlled trials utilizing theatrical and drama-based group curricula have also been studied with findings of moderate to small effects on behavioral and cognitive outcomes.

Technology-based interventions involving gaming and virtual reality are also emerging as potential treatments for social cognitive impairments in ASD. To date, game-based packages for facial processing, knowledge of emotional management strategies, and affect recognition/understanding have shown small effects on task-specific measures, with largely unknown effects on more distal measures, maintenance, or generalizability.

Taken together, promising targeted social cognitive group therapy are in the treatment development pipeline. Persistent concerns about size, generalizability, and durability of treatment effects remain to be addressed. In addition, the complexity and heterogeneity of ASD across development suggests interventions for higher-level skills such as social cognition must target multiple domains. Future research may consider multimodal interventions of empirically supported psychosocial interventions and promising pharmacotherapies to address complex social, behavioral, cognitive, and psychiatric needs of older children and individuals with ASD.

Definition

Social cognitive learning theory is a broad-ranging theoretical model of human behavior and is a major contribution to the social and behavioral sciences developed by Albert Bandura. Social cognitive learning theory posits that individuals are active agents in their development, not simply passive observers. In this model, there is a dynamic, continuous interrelationship between an individual's behaviors, the environment, and intrapersonal factors (i.e., cognitive, affective, and biological events) during development (Bandura 1986, 1999). The model seeks to explain the determinants of behavior as well as the dynamic conditions that can change behavior over time.

Historical Background

Social cognitive learning theory grew from Miller and Dollard's initial work in the area of social learning theory in 1941. Social learning theory provides a foundation for the development of social cognitive learning theory, embodying the idea that if an individual were motivated to learn a particular behavior, it would be learned through

observation and imitation of actions. Social cognitive learning theory expanded on this premise and is the product of decades of research and analysis of human functioning through the lens of learning frameworks. In 1963, Bandura and Walters wrote the seminal work *Social Learning and Personality Development*, which set forth the most comprehensive and complex account of social learning theory with its emphasis on observational learning and vicarious reinforcement. Social learning theory was a departure from prevalent models of development of the time, such as psychoanalysis and behaviorism (Grusec 1992). Psychoanalysts described behavior as driven by internal impulses, whereas behaviorists described behavior as completely shaped by the environment (Davis and Luthans 1980; Waller 2004). Social learning theory, while drawing on behaviorism in some ways, depicted behavior as a product of both internal factors and environmental factors and was the first major neo-behavior analytic theory to ascribe a role to cognition.

Bandura considered observational learning and imitation to be core components of social learning theory (Bandura 1969). Social learning theory posited that observational learning was a more effective method for behavioral change than direct learning or successive approximations (Grusec 1992). Social learning theory also conceptualized imitation differently than previous frameworks (Bandura and Walters 1963; Grusec 1992). In social learning theory, imitative responses did not need to be reinforced for observational learning to occur (Grusec 1992).

In 1986, Bandura renamed this framework from “social learning theory” to “social cognitive theory” with the publication of *Social Foundations of Thought and Actions: A Social Cognitive Theory*. The renaming of the theory demonstrated the new emphasis on cognitive processes. The new terminology helped to better represent the components and processes he had been advocating since the early 1960s (Grusec 1992). From 1986 on, Bandura consistently referred to the theory as social cognitive theory although the underlying framework remained the same.

This entry refers to the framework as “social cognitive learning theory” (SCLT) which combines the two names given by Bandura for the

framework and is used by some scholars (e.g., Money 1996). This term will be used throughout the remainder of this entry.

Current Knowledge

Core Concepts of SCLT

According to SCLT, there is a dynamic relationship between behavior, cognition, and other personal and environmental influences where each factor continually influences and impacts the others (i.e., triadic reciprocal determinism) (Bandura 1989). Individuals are both producers and products of their environment (Bandura 1989). That is, the way people interpret their behavior impacts and alters their beliefs and the environment they operate in, which then affects their future behaviors (Bandura 1986).

SCLT proposes that individuals are not simply passive observers but active agents in their development; therefore, it takes an agentic perspective to human functioning (Bandura 2005). That is, humans have control over their thoughts and behavior. They are active planners, forethinkers, self-regulators, and self-examiners by integrating their experiences to actively interact within their environment (Bandura 2005). The centrality of human agency is embodied by six core concepts that are fundamental to SCLT: the ability to symbolize and engage in forethought, vicarious learning, self-regulatory mechanisms, self-reflection, and self-efficacy (Bandura 1986). They place the individual as an active participant in the dynamic relationship between the environment, the individual’s cognitions, personal factors, and behaviors rather than a passive bystander of environmental variables or unconscious internal conflicts. These key concepts are described in more detail below.

Bandura noted that symbolization of thoughts allows people to store information that can be utilized for guiding future behavior (Bandura 1989). Symbols are mental representations of thoughts or images, which allow people to have structure, meaning, and continuity in their lives (e.g., language and gestures) to navigate their world, understand their environment, and problem solve (Malone 2002). For example, a child

develops a mental image of a smile and simultaneously assigns emotional and verbal meaning to this representation such as “a smile indicates that someone is friendly and approachable.” He later recalls and builds onto this “symbol” based on his experiences. The child’s internal representation of a smile influences him to respond positively to a smiling peer (e.g., by greeting or asking the peer to play). It is proposed that the use of symbols allows for individuals to model observed behavior (Bandura 1971).

The concept of forethought is that individuals can assess the likely consequences of their actions before they actually engage in an activity. Forethought utilizes symbolic representations in order to create future-directed plans (Bandura 2005). For example, when approaching a group of people engaged in a conversation, a person may mentally assess a range of strategies to enter the conversation. The choices can vary from appropriate such as making an on-topic comment (e.g., “Hi, that’s a funny story you just shared!”) to inappropriate (e.g., spontaneously dancing in front of the group to get their attention). The person assesses these choices and associated outcomes and then selects the strategy that would achieve the desired result (e.g., entering the conversation by commenting on the topic in order to be welcomed by the group). It is the mechanism individuals use to create a course of action, set goals, and predict the likely consequences of behavior, which motivate and influence future behavior (Bandura 2005).

Vicarious learning, also known as observational learning, is a departure from previous behavioral models of learning. Rather than depending solely on one’s own actions and experiences as a source of learning, Bandura suggested that individuals learn by observing and modeling others’ behavior. As such, individuals learn novel behaviors without the process of trial and error associated with direct learning (Bandura 1986); learning by example reduces error in behavior. Observational learning involves modeling behavior, particularly when the observed behavior is rewarded. It is guided by attention to the model’s actions, forming symbolic representations of these new behaviors in memory, performing the

observed behavior, and experiencing motivation to produce the actions. For example, a child may observe a friend successfully join a game by seeing how the friend first stands next to and watches other children play, waits for an appropriate pause, and finally expresses an interest in joining the game (e.g., “I want to play ball, too!”). The child observes that these behaviors were successful in entering a play situation. She later recalls and engages in similar behaviors when presented with a related social scenario. The developmental level of the learner may also influence learning and behavior, which has potential consequences for individuals on the autism spectrum (discussed in more detail in the next section). Vicarious learning facilitates the acquisition of information that guides behavior (Grusec 1992).

Self-reflection is the ability for people to evaluate their experiences. It is a mechanism that allows people to ultimately adapt behaviors and cognitions according to what they have seen, heard, felt, realized, and so forth. For example, after experiencing a difficult conversation with a friend, a teenager may recall the conversation. He evaluates whether the situation was handled appropriately by mentally reviewing his interactions as well as that of his friend. He assesses his feelings about the overall interaction and what actions he could have done differently to make the conversation more successful. Bandura identified self-reflection as the most “distinctly human” capability (Bandura 1986, p. 21).

Self-regulation refers to the ability to make adaptations to behavioral responses (Bandura 2003, 2005). Motivation and performance are not solely based on material incentives but social influences and personal standards as well (Bandura 2005). Personal standards are used as a yardstick for monitoring and comparing behaviors. If one’s behavior does not measure up to these standards, the individual will self-evaluate and adjust behaviors accordingly. For example, a girl sees her friend in a quiet library and enthusiastically greets her peer. The librarian at the library responds by exclaiming “shh!” The girl takes into account this information from her environment (i.e., the feedback from others that she needs to speak quietly) and adapts her behaviors

by speaking at a lower volume and standing closer to her peer to continue the interaction. The ability to engage in the self-regulation is shaped by the ability to accurately and reliably engage in self-observation and self-monitoring (Bandura 2003).

Self-efficacy, the belief that one is able to produce desired outcomes, is fundamental to SCLT. It is viewed as a foundation for motivation, confidence, emotional and psychological well-being, and understanding and explaining people's actions (Bandura 1977; Bandura et al. 1977). Bandura (1986) defines self-efficacy as "people's judgments of their capabilities to organize and execute courses of action required to attain designated types of performances" (p. 391); so, it is a belief about one's capabilities, rather than necessarily knowing what to do. For example, a person with high self-efficacy about his social skills will feel confident in his ability to successfully enter social conversations at a party. Consequently, he will be more likely to try entering new social situations and interact with unfamiliar people because he is sure that his strategies will lead to positive responses from others. Self-efficacy is essential for behavior change (Bandura and Walters 1963; Bandura 1977) because a person's belief in the capability of producing a desired outcome influences the incentive to act or change. Poor perceptions of self-efficacy will weaken motivation to persevere in the face of challenges. Self-efficacy beliefs are developed through successful experiences in particular situations (defined in SCLT as mastery of experiences), seeing a person similar to oneself succeed (vicarious experiences), being told that one is capable of succeeding (social persuasion), and positive interpretation of an event (reduction of stress reactions and negative affect) (Bandura 1994).

In summary, SCLT posits that specific cognitive processes mediate behaviors. In both direct and indirect learning experiences, the environment and thoughts affect one another in an intertwined fashion. These theoretical underpinnings provide an overarching understanding of human development. The theory has been highly influential in psychology, providing foundations for mid-level theories as well as intervention programs. It has provided a conceptual framework for

some mid-level cognitive behavioral theories because it embraces the combined importance of external factors (i.e., experience and social contexts) and internal factors (i.e., cognition) in understanding and predicting human behavior.

SCLT in Understanding Autism Spectrum Disorder

As outlined above, SCLT suggests that an individual's development and functioning relies on one's ability to symbolize, to engage in forethought, learn vicariously, self-regulate, self-reflect, and experience self-efficacy (Bandura 1986). Individuals with ASD may have limitations in a number of these areas, and these impairments likely have important consequences on their development, behavior, and capacity to benefit from intervention strategies.

Impairment in the ability to symbolize, for example, is consistently reported in ASD (e.g., Bernabei et al. 1999). These challenges are evidenced by lack of imagination or pretend play (Jarrold 2003; Varga 2010), deficits in theory of mind (Peterson et al. 2009), and limited use of gestures and other nonverbal means of communication (Shumway and Wetherby 2009). Such deficits impede one's ability to make sense of perceived information from people and their environment, create mental representations, and apply this to their behavioral repertoire. This can have detrimental consequences in terms of social cognitive development and understanding one's social milieu.

Evidence suggests that individuals with ASD exhibit atypical visual scanning and attention (Brenner et al. 2007), which impacts the ability to benefit from observational learning. For example, individuals with ASD may have difficulty processing visual information using a top-down strategy (Loth et al. 2011). Whereas typically developing individuals are able to use prior knowledge and context to perceive fragmented or degraded images as recognizable stimuli (e.g., faces), individuals with ASD often attend to local features of a stimulus when processing visual information (e.g., Nakahachi et al. 2008; Rondon and Deruelle 2007). In other words, individuals with ASD may attend to details rather than relying

on prior knowledge and experience and context to interpret ambiguous stimuli. In addition, evidence suggests that rather than attending to pertinent features of a face (e.g., eyes), individuals with ASD tend to devote attention to the mouth when viewing faces (e.g., Klin et al. 2002). It has been hypothesized that these patterns of attention contribute to face processing and recognition deficits associated with ASD (Golarai et al. 2006), demonstrating how atypical visual attention impacts interpretation of social stimuli. Atypical processing of social stimuli undoubtedly impacts the ability to garner important information from one's environment, impeding successful observational learning. It has also been demonstrated that individuals with ASD fail to orient to social stimuli (e.g., their name being called; Dawson et al. 1998), indicating they may not be motivated to attend to social stimuli and likely miss critical cues in their environment. Failure to attend to social cues suggests that individuals with ASD perceive, assimilate, and are shaped by a set of informational cues that differs from typically developing individuals. Studies of young children have also demonstrated that ASD is characterized by challenges with disengagement of attention, or difficulty disengaging from one stimulus and shifting eye gaze to a new stimulus (Landry and Bryson 2004; Zwaigenbaum et al. 2005). This impedes successful visual scanning of one's environment and ability to process salient stimuli, which are critical features of observational learning. Finally, it has consistently been reported that individuals with ASD have impairments in joint attention, or the sharing of attention between two people to reference a stimulus, and this finding is considered a token feature of ASD (e.g., Mundy et al. 2009). This skill is fundamental to learning about one's environment and developing symbolic thought. Within a SCLT framework, deficits in these areas may have serious implications in terms of one's ability to learn from their environment, develop appropriate social skills, and function in everyday life.

According to SCLT, individuals with ASD may experience further disadvantage given their

impaired imitation (i.e., modeling) skills (Williams et al. 2004). Evidence suggests that mirror neuron dysfunction may partially account for these difficulties (e.g., Williams 2008). Mirror neurons fire not only when an individual is actively imitating but also when observing others executing the same actions (e.g., Iacoboni and Dapretto 2006). Impairments in this neural system would suggest that in addition to the impact on the ability to imitate, individuals with ASD may not process another's actions when observing them. This can have detrimental consequences on the capacity to learn from one's environment and integrate social information into their schema.

Another aspect of autism is the failure to develop developmentally appropriate friendships (Bauminger and Kasari 2000; Chamberlain et al. 2006). This challenge may impact both motivation in observational learning and development of self-efficacy. Motivation, in observational learning, refers to the incentive to reproduce the observed behavior (Bandura 1986; Malone 2002). The incentive for observational learning behavior is often a form of social reinforcement or approval. Social reinforcement or approval may be less motivating for individuals with autism due to social deficits, such as social and emotional reciprocity and developmentally appropriate relationships with peers (Bauminger and Kasari 2000; Chamberlain et al. 2006).

These challenges associated with ASD have consequences on one's capacity to perceive and assimilate salient information from their environment, thereby impeding appropriate social development according to SCLT. Intervention strategies targeted at these specific deficits (e.g., visual attention, imitation) may provide individuals with ASD with the opportunity to more efficiently and successfully acquire information from their environment and from other people. For example, Faja and colleagues (Faja et al. 2008) developed a computerized face-training program to facilitate proper visual attention and improved face recognition in individuals with ASD. And, teaching joint attention to young children with

autism has led to improvements in related skills, including imitation and spontaneous speech (Whalen et al. 2006). These examples demonstrate how targeting skills related to SCLT can have broad effects on social functioning in ASD.

SCLT and Interventions for ASD

Video modeling is a form of behavioral intervention used to target numerous behaviors in individuals with autism. In video modeling, the model is shown on a video rather than live, in an attempt to change a behavior or help the individual with autism learn a new, appropriate behavior (Grant and Evans 1994). Generally, the individual views the video, observing the model engaging in the appropriate behavior, and then imitates the target behavior (Charlop-Christy et al. 2000). Video modeling has been shown to be an effective, and rapid, behavioral intervention in numerous single-case design studies. It has been shown to be effective for low- and high-functioning individuals with autism (Charlop-Christy et al. 2000). Video modeling incorporates many tenets of SCLT in order to promote behavioral changes in individuals with autism.

Primarily, video modeling incorporates the four processes required for observational learning, attention, retention, symbolic representation, and motivation, in order to enhance the effectiveness of observational learning for individuals with autism. Charlop-Christy et al. (2000) found that video modeling was a more effective behavioral intervention than in vivo modeling for individuals with autism. Video modeling improved the attention of individuals with autism as compared to in vivo modeling. Many individuals with autism have difficulty with stimulus overselectivity, failing to perceive the entire stimulus and its relevant cues. Video modeling can counteract this problem by focusing in on the specific stimulus cues necessary to learn the target behavior (Charlop-Christy et al. 2000). Video modeling minimizes attentional requirements, allows the individual to focus on the appropriate stimuli repeatedly, and thereby facilitates successful acquisition of the target

behavior and its maintenance in memory (Corbett and Abdullah 2005).

Video modeling reduces the amount of symbolic representation necessary for observational learning to occur by decreasing the amount of language present in the video. The individual with autism is only required to listen to and comprehend minimal, if any, language (Sherer et al. 2001), which reduces or eliminates the challenge of symbolically representing language.

Furthermore, motivation may enhance the effectiveness of video modeling as a behavioral intervention because video viewing is an easy, low-demand activity, which many individuals with autism engage in at home (Shipley-Benamou et al. 2002). This method of teaching new information is less structured than many behavioral interventions and creates a more casual learning environment, which may encourage successful acquisition of new information (Charlop-Christy and Daneshvar 2003). Studies by Charlop-Christy et al. (1998) and Schreibman (1988) found that individuals with autism often repeat phrases from videos, television, or commercials; watch the same video multiple times; or persevere on a certain television show or video. These findings suggest that video viewing is intrinsically reinforcing for some individuals with autism (Charlop-Christy et al. 2000).

Video modeling has been used to target a wide range of skills in individuals with autism. A review of 19 studies on video modeling and autism by Delano (2007) found that video modeling proved effective in addressing social-communicative skills, functional skills, perspective-taking skills, and problem behavior. Haring et al. (1987) used video modeling to promote the development of purchasing skills to individuals with autism. Video modeling was used by Charlop and Milstein (1989) to promote conversational speech to children with autism. Grant and Evans (1994) showed that video modeling enhanced social initiation and appropriate toy play in children with autism. Studies by Charlop-Christy (1993, 1994) demonstrated that

play behaviors, such as independent play, cooperative play, and pretend play, improved through a video modeling intervention. Video modeling also improved the level of verbal and motor play response in children with autism (D'Ateno et al. 2003) and reciprocal play skills (Nikopoulos and Keenan 2004). Lastly, a few studies have used video modeling to reduce disruptive and challenging behaviors (Shipley-Benamou et al. 2002; Buggey 2005).

SCLT is a core foundation of cognitive behavioral therapy (CBT). Interventions using CBT for individuals with autism (e.g., Chalfant et al. 2006; Reaven et al. 2009; Sofronoff et al. 2005; Wood et al. 2009) emphasize attention, motivation, self-reflection, self-regulation, and self-efficacy. In CBT, active participation by the child to develop and practice coping skills is key. Studies have shown CBT to be an effective intervention in reducing anxiety in children with high-functioning autism and Asperger's disorder (Chalfant et al. 2006; Reaven et al. 2009; Sofronoff et al. 2005; Wood et al. 2009).

A fundamental component of CBT with individuals with autism is developing awareness and identification of emotion feelings in order to promote greater self-regulation of behavior. Self-reflection and self-regulation are often challenging for individuals with autism; therefore, these are taught to participants in CBT by practicing the identification of cues of emotion (e.g., through body feelings), which is one method of self-reflection (Chalfant et al. 2006; Reaven et al. 2009; Wood et al. 2009). In addition, the interventions underscored teaching the connections between feelings and thoughts.

Another component of SCLT utilized in CBT with individuals with autism is the promotion of self-efficacy. The work by Wood et al. (2009) targeted improving self-efficacy as a fundamental component of the CBT intervention. Wood et al. (2009) and Drahota et al. (2011) discussed the importance of improving self-care in individuals with autism in order to increase individuals' mastery experiences and ultimately improve self-efficacy. The focus on improving self-care is important because researchers have found

adaptive skill deficits in individuals with autism (Rodrigue et al. 1991). As mentioned earlier, according to SCLT, one way of improving self-efficacy is through mastery experiences. CBT interventions also promote mastery experiences in feared situations. For example, Wood et al. (2009) and Reaven et al. (2009) used a hierarchy of feared situations where participants are rewarded as they try increasingly challenging (feared) situations. The use of a hierarchy allows the participants to start with less fearful situations and work their way up to more challenging feared situations, gaining confidence with small steps as they go. The successful achievement of the feared situations in vivo in CBT allows the participant to systematically confront and succeed in anxiety-provoking situations, which systematically increases the participants' self-efficacy.

Future Directions

SCLT provides an informative framework for understanding human functioning and may have relevance to the impact of ASD symptoms on learning and adaptive behavior in individuals with autism. Video modeling and CBT are two interventions that are influenced by SCLT in treating ASD symptoms, and each has evidence of efficacy. Future research with individuals with autism may consider incorporating SCLT principles to inform interventions in order to improve skill learning and comprehension. By creating interventions that consider how deficits in autism impact symbolic representations, forethought, vicarious learning, self-reflection, self-regulation, and self-efficacy, the interventions may be able to better achieve their goals and meet the needs of affected individuals.

Synonyms

[Reciprocal communication](#)

Definition

Social communication is a broad term that describes the vast amount of verbal and non-verbal behaviors used to interact with other people. Examples of the verbal and nonverbal behaviors are (but are not limited to) speech, prosody, gestures, and facial expressions. These behaviors can be used to initiate or respond to joint attention, to share emotion with others, or to signal when an individual wants the attention of another person, along with many other uses.

A deficit in social communication is a diagnostic characteristic of children with ASD.

Social Communication Questionnaire

Anne Snow

Child Study Center, Autism Program, Yale University, New Haven, CT, USA

Synonyms

[Autism screening questionnaire \(ASQ\); SCQ](#)

Description

The Social Communication Questionnaire (SCQ), formerly known as the Autism Screening Questionnaire (ASQ), is a screening measure that was developed to identify symptomology associated with autism spectrum disorder (ASD; Rutter et al. 2003a). It is widely recognized in the field as a recommended screening measure for ASD (Coonrod and Stone 2005; Hus and Lord 2011).

The SCQ contains 40 *yes/no* items that are completed by the parent or primary caregiver. It is applicable to individuals whose chronological age is over 4 years, provided that their mental age is over 2 years. A body of research is accumulating that aims to determine the utility of the SCQ in young children, however (e.g., Corsello et al. 2003).

There are two versions of the SCQ. The Lifetime version inquires about the individual's entire developmental history, and the items in the Current version refer to the individual's behavior in the most recent 3-month period. The Lifetime form should be used for diagnostic screening purposes, and the Current form is appropriate to use when the goal is to understand an individual's current level of ASD symptomology, such as when evaluating treatment or educational plans.

Scoring of the SCQ results in a total score that is compared to a cutoff score developed from the Lifetime form. The total score is calculated by summing the item responses as indicated on the scoring form that is provided as part of the SCQ protocol. For each item, a score of 1 is given for abnormal behavior, and a score of 0 is given for its absence. All items are given equal weight in determining the total score. Different scoring procedures are used for verbal and nonverbal individuals. For verbal individuals, six items asking about language abnormalities are included in the total score, whereas these items are disregarded for individuals who are nonverbal. A cutoff score of 15 or greater identifies individuals who are likely to have an ASD, indicating that more thorough evaluations are warranted. Subscores that correspond to the three symptom domains of ASD (social abnormalities, communication abnormalities, and restricted, repetitive, and stereotyped behavior) can also be calculated. However, it must be noted that due to insufficient research on these subscores, they should be used for research purposes only (Rutter et al. 2003).

Historical Background

The SCQ was originally developed as a companion to the Autism Diagnostic Interview-Revised (ADI-R; Rutter et al. 2003b). It was designed as a

shorter version of the ADI-R, which is a 93-item structured interview. Items from the ADI-R with discriminative diagnostic validity were chosen for the SCQ. Selected items assess the three symptom domains of ASD: reciprocal social interaction, communication, and restricted, repetitive, and stereotyped patterns of behavior. Items were also selected based on the extent to which the behavior in question was readily observable by the caregiver. The wording of the items was also modified to increase the clarity of the item for parents.

Psychometric Data

Standardization data for the SCQ were collected from 200 individuals between the ages of 4–40 years (Berument et al. 1999). The sample included 160 individuals with ASD and 40 with nonspectrum disorders. Validity of the SCQ was assessed by analyzing its factor structure, the ability of SCQ items and total score to discriminate ASD and non-ASD groups, and correlating SCQ scores with those from the ADI-R. Factor analysis of the SCQ supported a four-factor structure consisting of the following factors: social interaction, communication, abnormal language, and stereotyped behavior. Item analyses indicated that 85% of the items differentiated between ASD and non-ASD individuals at a statistically significant level. Similarly, total scores on the SCQ were significantly different between ASD and non-ASD groups. Examination of total scores indicated a cutoff score of 15 for discriminating ASD from non-ASD diagnoses. A cutoff of 22 was suggested to distinguish between autism and other ASDs. Comparisons to the ADI-R revealed significant correlations between all domains of the two instruments as well as the total scores. Two additional studies support the concurrent validity of the SCQ and ADI-R. Both found good agreement between the SCQ and the ADI-R diagnostic categories but found lower agreement between the SCQ and ADI-R at the item level (Rutter et al. 2003). In sum, the standardization data supported the validity of the SCQ and suggested strong psychometric properties.

A subsequent study of the diagnostic validity of the SCQ examined its performance in a sample

of 157 children ($n = 71$ autism, $n = 49$ ASD, $n = 37$ non-ASD) (Corsello et al. 2003). Total mean scores between diagnostic groups were in the expected direction, with the autism group earning the highest scores, followed by the ASD group, and the non-ASD group had the lowest mean total scores. The authors stated that these results suggest that the total SCQ score corresponds with diagnosis and is a reasonable index of symptom severity. However, there is also evidence that the diagnostic validity of the SCQ appears to be enhanced when it is used in conjunction with observational measures such as the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 1999) (Corsello et al. 2007, in Hus and Lord 2011).

Whereas the literature agrees that the SCQ is a reliable and valid screening tool for individuals 4 years and older, adaptations may need to be made when using the SCQ in children under this age. Corsello and colleagues have suggested that when using the SCQ with children under the age of 5 years, the cutoff score should be lowered in order to improve the sensitivity of the measure (Corsello et al. 2007, in Bishop et al. 2008). Another option is to use the Current version of the SCQ, which can be used with children as young as 2 years (Hus and Lord 2011).

Clinical Uses

The authors of the SCQ cite three main uses of the instrument (Rutter et al. 2003). First, it can be used as a screening instrument to detect individuals who are in need of a clinical assessment for ASD. Second, SCQ scores can be used as a measure of overall ASD symptomology between different groups, such as children with other developmental disorders. Third, scores can be used as an index of severity of ASD symptoms between groups or in one group over time, as in the case of treatment studies.

When using the SCQ as a screening instrument for ASD, it must be noted that the SCQ does not replace a diagnostic assessment. It should not be used on its own as a diagnostic tool (Rutter et al. 2003).

Definition

A core feature of Autism Spectrum Disorder (ASD), social disability, does not remit with development (Sigman and Ruskin 1999) and may in fact worsen during adolescence when social demands are heightened (Picci and Scherf 2015). “Social interventions” are a diverse group of therapeutic efforts intended to improve social functioning, including ability to make friends, achieve interpersonal intimacy, and navigate novel social situations. Social interventions target improved social competence in numerous ways, such as directly teaching specific prosocial skills, reducing competing or socially inappropriate behaviors, or training in social cognition believed to contribute to improved social functioning (e.g., emotion recognition, theory of mind). There are multiple clinical approaches to social interventions stemming from varied theoretical

orientations. Social interventions are also sometimes referred to as social skills training programs or relationship-based interventions.

Historical Background

Since Kanner’s (1943) original description of autism, social difficulty has been thought of as a prominent, and arguably unifying, characteristic of ASD. About three decades later, clinical scientists began to investigate the possibility of social interventions to improve these problems (Bemporad 1979; Stokes 1977). Social interventions have historically been firmly rooted in behaviorism, primarily operant conditioning in which behaviors are learned via repeated pairing with reinforcement or reward. Although often a component of treatment for people with ASD, social interventions are also often useful for individuals who struggle with other problems, such as Attention-Deficit/Hyperactivity Disorder (ADHD), depression, and shyness (e.g., de Boo and Prins 2007; Greco and Morris 2001; Segrin 2000).

Gary Mesibov (1984) extracted key elements (i.e., modeling, coaching, role playing with feedback) from established social skills training programs and applied them to develop a group social skills treatment model for verbal adolescents and adults (age 14–35 years) with ASD. Shortly thereafter, Williams (1989) implemented a similar group format for an intervention using modeling, role-playing, and playing interactive games. Ten children and adolescents (age 9–16 years) with ASD completed 4 years of a weekly 45-minute social skills training session. These early reports sparked a scientific and clinical curiosity that still persists to this day.

Lovaas (1987) was the first to describe behavioral modification treatment for young children with ASD, which is based on operant theory and entails intensive therapy across settings. This intensive instruction requires the child to actively engage with his or her social environment, while being provided with consistent reinforcement for adaptive behaviors and interactive play with peers. As a follow-up to this early study, McEachin et al. (1993) looked specifically at social functioning

and found that treatment group participants significantly improved in the area of socialization, based on parent report, relative to control group participants.

Despite these early and informative research studies, a lack of readily available social intervention programs for ASD existed well into the 1990s (Klin and Volkmar 2000). Toward the end of the twentieth century, a broader range of social skills interventions was being developed and scientifically investigated, including self-management techniques (Koegel et al. 1992) and sociodramatic play-based approaches (Thorp et al. 1995). The science was also maturing, as evidenced by more rigorous data collection efforts and recognition of the need for well-characterized samples along with manual-based programs to allow for replication.

Current Knowledge

Several published meta-analyses on social interventions for individuals with ASD (e.g., Bellini et al. 2007; Wang et al. 2013), along with the National Professional Development Center (NPDC), which is dedicated to promotion of evidence-based practices with individuals with ASD, have sought to determine the impact of social interventions for people with ASD. Reichow and Volkmar (2010), in their review, determined that social skills groups could be considered an established, evidence-based intervention. Indeed, group-based interventions are arguably the most common modality of social intervention. Although group-based interventions have been found to be modestly effective, gains do not necessarily materialize at the level of social behaviors in naturalistic settings (e.g., school) (Gates et al. 2017). In terms of differential impact of constituent aspects of intervention, it appears that video modeling (i.e., using self or other to model skill or behavior being taught via video), a technique employed in many social interventions, is one of the most effective components (e.g., Wang and Spillane 2009). Perhaps the most consistently reported finding from the applied studies on social interventions for ASD is that there

is considerable variability in terms of treatment response across participants.

At the time of this publication, there are several social intervention curricula for ASD. As an exhaustive review is beyond the scope of this entry, we will provide a brief overview of research on selected curricula. Readers who wish more in-depth or detailed information are encouraged to read information provided in the suggested selected readings. Groups that apply a cognitive-behavioral approach to train social competence are commonly used. The *Program for the Education and Enrichment of Relational Skills* (PEERS), a group-based program rooted in cognitive-behavioral therapy, was initially developed for adolescents with ASD (Laugeson et al. 2012) and has since been extended to both preschool-age children and adults (Gantman et al. 2012). Results from several randomized controlled trials (RCTs) have supported the efficacy of PEERS (Laugeson and Park 2014). The *summerMAX* program is an intensive, 5-week long, behaviorally based treatment for school-age children. It has demonstrated feasibility and efficacy in both university (Lopata et al. 2010) and community agency settings (Thomeer et al. 2016).

Theatrical, or drama-based interventions, have also been developed to improve social competence in youth with ASD. Theoretically, such interventions not only promote skill generalization (perhaps via enhanced interaction with typical peers) but also increase perspective-taking and social cognition (e.g., Corbett et al. 2016). The *Socio-Dramatic Affective-Relational Intervention* (SDARI; Lerner et al. 2011) is a brief (6-week) curriculum, associated with modest improvement in ability to detect emotions. The *Social Emotional NeuroScience Endocrinology Theatre* (SENSE) Theatre (Corbett et al. 2011) combines peer mediation (i.e., training similar-age peers to engage with, and help, the learners with ASD), behavioral skills training, and drama to improve social skills. In an RCT, participants who completed SENSE Theater showed significant improvements, relative to wait-list control participants, on several indicators of social behavior and cognition (Corbett et al. 2016).

There are several other types of social interventions that show considerable promise as being effective for some individuals with ASD. Social Stories (Gray 1998) are a straightforward approach used to explain social situations and behaviors to people with ASD. Social stories are often used to promote appropriate social skills and decrease problem behaviors. Results from several single subject and small sample studies have been quite positive (e.g., Dodd et al. 2008; Sansosti and Powell-Smith 2008). Pivotal Response Treatment (PRT) is another type of intervention, derived from the principles of applied behavioral analysis (ABA), for people with ASD (Koegel et al. 2006). Instead of targeting distinct individual behaviors, PRT focuses on pivotal areas of a child's development. The goal of PRT is to provide learning opportunities within the context of the child's natural environments.

Future Directions

The research base on social interventions has matured tremendously over the last decade. We have a better appreciation for the differential impact of various treatment components, and consumers and practitioners have considerable choice in terms of available packaged curricula. Nevertheless, there are many as-yet unanswered questions related to the clinical impact of social interventions.

Recently, research has been undertaken that will inform our understanding of predictors of treatment response. This work is critical for personalized treatment planning. Clinical science has long-appreciated the fact that response to even our best treatments is not uniform across clients. This is true also for targeting social improvement in people with ASD. By understanding both predictors and moderators of response, we can begin to tailor approaches to fit the client (cf, personalized medicine).

Unfortunately, the vast majority of the research in this area has been with preadolescent children. By comparison, research on the feasibility and efficacy of social interventions for very young children or adults, as well as adolescents to some

degree, is limited. It will be imperative that we begin to explore how to effectively intervene with older adolescents and adults especially, given the pervasiveness of social disability and its relationship to later impairment as well as co-occurring problems (e.g., anxiety). This will not be a straightforward "upward" extension given that some of the best-supported strategies (e.g., peer-video modeling and mediation) rely on availability of similar age peers and other support systems. Additionally, the nature of adult social interaction is incredibly variable across contexts, and there are fewer opportunities for face to face interaction practice with unfamiliar people after exit from secondary school.

Emerging directions for social interventions are diverse. As described by Wieckowski and White (2017), there is growing evidence for the feasibility and utility of technology-based interventions. On the whole, these interventions have been found to be acceptable to end-users (e.g., children with ASD) and target a host of measurable mechanisms underlying change in social function (e.g., facial emotion recognition). For example, improved ability to detect others' emotions may contribute to more empathic responding and prosocial behavior. Examples of such interventions include *Mind Reading: The Interactive Guide to Emotions* (Golan and Baron-Cohen 2006), the *Junior Detective Training Program* (Beaumont and Sofronoff 2008), and *Let's Face It!* (Tanaka et al. 2010). More research is needed to understand the clinical impact and generalizability of technology-based social interventions.

As the field continues to mature with respect to effective social interventions with ASD, we need to focus simultaneously on expansion as well as refinement. Regarding the former, it is critically important that novel approaches be developed (e.g., technology) as this will allow greater choice to consumers and, ultimately, aid dissemination. We do not expect even a well-established treatment to work for every client or patient. The heterogeneity in cause and presentation of ASD mandates diversity in availability of treatment approach. Regarding refinement, as we continue to deepen our understanding of the processes that underlie social impairments, ability to target key

mechanisms will be improved (Lerner et al. 2012) and, likewise, there is greater appreciation of the importance of dismantling research to identify the “critical elements” of efficacious interventions. In the future, we will see more equivalence testing of interventions, in order to evaluate relative superiority, and adaptive trials in which participants are assessed at regular intervals, in order to determine how allocation (treatment assignment) will proceed. In summary, the field has made great strides with regard to social interventions for people with ASD, and we are hopeful about the future with respect to clinicians’ ability to adopt a scientifically informed approach to determining what type of intervention works best for whom, across the lifespan, for people with ASD.

Social Language Development Test

Linda Bowers and Rosemary Huisigh
LinguSystems, Inc, East Moline, IL, USA

Synonyms

SLDT-A; SLDT-E; Social language development test-adolescent; Social language development test-elementary

Description

The tests of social language development—elementary and adolescent (Bowers et al. 2008, 2010) are diagnostic tests of social language skills. They are designed to determine the role language development plays in the acquisition of social understanding for students from the ages of 6.0–17.11 years from the following educational settings: regular education (no active IEP) and special education (active IEP). Students with a diagnosis of autism and delayed language development were included in the item pool and standardization studies.

The testing materials are as follows:

The social language development test—elementary (SLDT-E) includes an examiner's manual, the scoring standards and example responses book, a picture stimuli book, and test forms. Ages include 6.0–11.11 years.

The SLDT-E is comprised of four subtests designed to differentiate how students with language impairments and autism differ from their typically developing peers in social cognitive processing, in identifying feelings of participants in a conflict, in identifying and evaluating strategies to overcome obstacles, and in knowing when a conflict is resolved. The subtests are the following: (a) making inferences, (b) interpersonal negotiation, (c) multiple interpretations, and (d) supporting peers. Each subtest has 12 items.

Many children with language impairments (LI) exhibit poor social interaction with others, and these social differences may appear as early as preschool and continue or intensify as these children mature (Brinton et al. 2004; Cohen et al. 1998; Craig 1993; Fujiki et al. 1997; Hadley and Rice 1991). A tool that would pinpoint areas of strengths and weaknesses would guide speech-language pathologists (SLPs) in determining appropriate intervention goals and objectives. Tasks in this test focus on taking someone else's perspective, making correct inferences, negotiating conflicts with peers, being flexible in interpreting situations, and supporting friends diplomatically.

The social language development test—adolescent (SLDT-A) includes an examiner's manual, the scoring standards and example responses book, a picture stimuli book, test forms, and an audio CD used with subtest E: interpreting ironic statements. Ages include 12.0–17.11 years.

The SLDT-A is comprised of five subtests designed to differentiate typically developing elementary children from typically developing adolescents, typically developing adolescents from language-impaired adolescents, and language-impaired adolescents from adolescents identified with high-functioning autism. The subtests are the following: (a) making inferences, (b) interpreting social language, (c) problem solving (stating and justifying solutions), (d) social interaction, and (e) interpreting ironic statements. Each subtest has 12 items each. Three of the subtests have two questions per item.

Language is the skill that is central to engaging in all aspects of peer relationships. Students with limited language skills are susceptible to misinterpretations and have more difficulty participating in the highly verbal, rapidly delivered social processes used in peer group formation (Gallagher 1993). They often have difficulty maintaining friendships, negotiating conflict, and getting along with others. Tasks in this test focus on taking someone else's perspective, making correct inferences, solving problems with peers, interpreting social language, and understanding idioms, irony, and sarcasm.

These tests do not address all aspects of social language or pragmatic skills. Rather, they focus on social interpretation and interaction with peers and/or friends. For both tests, the items are not arranged in order of difficulty because, as of yet, no hierarchy is established for these tasks. For this reason, there are no basals or ceilings; each subtest is administered in its entirety to every student.

The tests begin with the first item in subtest A. Explicit directions for how to administer the items are provided. Demonstration items are provided for each subtest. These items may be altered or explained to show the student how to respond.

Following the demonstration item, each subtest begins with item 1 regardless of the student's age. Each item is presented verbally. The only exception is subtest E: interpreting ironic statements on the SLDT-A. An audio CD is used to administer this subtest.

Allowable prompts, used only as worded, are listed on the test forms. These are used if the student's response is unclear. These prompts are not used to give the student "a second chance" after a clear, complete, but incorrect response.

More than one testing session is allowable if the break between sessions occurs upon completion of a subtest and all of its questions.

The test examiner must be a trained professional familiar with language disorders (e.g., speech-language pathologist, psychologist) as they require careful interpretation of responses by the examiner.

Subtests A in both tests tap the student's ability to infer what someone in a photo is thinking. The student also states the visual clues that facilitated making the inference. Skills assessed in these subtests include the ability to:

- Detect nonverbal and context clues in a picture of a person or people
- Assume the perspective of a specific person in a picture
- Infer what the person is thinking
- Express the person's thought as a relevant, direct quotation
- State the visual clue that suggests what the person is thinking

A score of 1 or 0 is assigned to each response based on the relevancy and quality of the response. For the SLDT-A, the student must provide an appropriate response for both questions to earn a score of 1.

SLDT-E Subtest B: Interpersonal Negotiation asks the student to imagine being involved in a given conflict with a friend. The student states the problem (task a), proposes an appropriate solution (task b), and explains why that would be a good solution (task c). No pictures or photos are used for this subtest. Skills assessed in this subtest include the ability to:

- Understand a short passage about a conflict with a friend
- Infer the perspective of each person in the conflict
- State the problem clearly
- Propose a solution
- Explain why that would be a good solution

A score of 3, 2, 1, or 0 is assigned to each response based on relevancy and quality.

SLDT-A Subtest B: Interpreting Social Language asks the student questions about how people communicate. The student is asked to give an example and an appropriate context in which the type of communication would be used. Skills assessed include the ability to:

- Demonstrate actions
- Tell an appropriate reason or use for an action
- Think/talk about language
- Interpret figurative language including idioms

A score of 1 or 0 is assigned to each response based on relevancy and quality.

SLDT-E Subtest C: Multiple Interpretations asks the student to provide two distinctively different, plausible interpretations of the same photo. Skills assessed in this subtest include the ability to:

- Logically interpret a situation in a photo in two different ways

A score of 1 or 0 is assigned to each response, based on relevancy and quality.

SLDT-A Subtest C: Problem Solving (Stating and Justifying Solutions) asks the student to solve a problem by stating and justifying a logical solution. The student must give both a solution and a justification. Skills assessed include the ability to:

- State an appropriate solution to a problem in a situation with a peer
- Justify the solution
- Negotiate conflicts with peers
- Take the perspective of the other person in the situation
- State the conflict from a mutual perspective

A score of 1 or 0 is assigned to each response based on relevancy and quality.

SLDT-E Subtest D: Supporting Peers asks the student to take the perspective of someone involved in a situation with a friend. The student tells what to say in reaction to the friend's situation. Responses receive credit based on the degree of support they offer to the friend, not on the truthfulness.

Being truthful is a basic maxim of interpersonal communication (Grice 1980), yet speakers are also expected to help, not hurt, their communicative partners (Lakoff 1973; Sweetser 1987). Telling white lies successfully requires reconciling these apparently contradictory communication rules and knowing when and how to adapt them to suit various social situations (Talwar et al. 2007).

A score of 4, 3, 2, 1, or 0 is assigned to each response based on relevancy and quality of support for a friend.

SLDT-A Subtest D: Social Interaction asks the student to listen to situations and answer questions about them. In some situations, an appropriate response may include a dishonest or rude remark. Skills assessed include the ability to:

- Listen to short passages
- Understand social interactions with peers
- Provide an appropriate, supportive response
- Ignore the situation (when doing nothing is the best option)

A score of 1 or 0 is assigned to each response based on the relevancy and quality of support for the situation.

SLDT-A Subtest E: Interpreting Ironic Statements asks the student to listen to some situations on a CD. The narrator reads the situations and asks what someone means at the end of each one. Research on intonation features associated with irony is inconsistent, and ironic speech does not necessarily include "signature acoustic features" (Bryant and Fox Tree 2005; Nakassis and Snedeker 2002). For this reason, the assumed features of irony (e.g., exaggerated pitch) were "toned down" so that the student must rely on context discrepancies and other context clues to

determine the ironic meaning of a statement. Our research proved that including exaggerated intonations made the task too easy for the age range of this test. Skills assessed included the ability to:

- Understand common idioms used in everyday language
- Reject the literal meaning of the statement
- Understand the speaker's belief
- Judge the speaker's attitude
- Recognize sarcasm and interpret irony

A score of 1 or 0 is assigned to each response based on the relevancy and quality.

Historical Background

In 1983, we published a test of pragmatics called the interpersonal language skills assessment (ILSA) by speech-language pathologists, Carolyn Blagden (now LoGiudice) and Nancy McConnell. This test of pragmatic behaviors looked at interaction of 8–13-year-olds while playing a board game. The authors wanted to determine if there was age progression and reverse age progression on such behaviors as advising, commanding, accusing, deprecating, justifying, and supporting. They found that in general, as students got older, their outright negative comments decreased while their sarcasm increased. They also found out that comments with grammar or semantic errors decreased with age. Although some speech pathologists were curious about the skills assessed in the ILSA, there was a general lack of interest from the field. By 1989, this test was out of print.

Between 1990 and 2008, we continued to scour the research on pragmatic/social language skills. Our hypothesis was that children develop social "governors" as they mature. Over time, research articles about peer support, negotiating, making inferences, and interpreting facial expression and body language appeared in the literature. We also read research about the development of these skills in children on the autism spectrum and on children who had language disorders but who were not classified as autistic.

Despite a growing body of research, as of yet, there is no well-recognized, research-based developmental model for children learning social interaction skills. That may be because the following:

- Adults seem to have mastered social interaction without any conscious effort or formal instruction.
- Much of social language is abstract and covert and cannot be observed directly. We can only assume what someone else is thinking based on nonverbal cues, background knowledge, and the person's words and actions.

We do know that children with language impairments exhibit poor social interaction with others. We decided that if speech pathologists had an effective, standardized tool to assess the social interaction skills of students that would also pinpoint areas of strengths and weaknesses, it would guide the SLP in qualifying students for therapy and help in determining appropriate intervention goals and objectives.

We began writing and rewriting items and testing and retesting children. Our item pool results showed us the need for a scoring system that was sensitive to subtle changes in verbal behavior. The standardization studies proved the scoring standards were correct but that further refining was necessary. These tests represent the important data we gathered and we believe are a good start toward identifying children with social language differences.

Psychometric Data

Item pool and standardization studies were conducted for both tests. The items and subtests for both tests were subjected to rigorous statistical analyses in these studies.

The item pool and standardization studies for each test included subjects from regular education, special education, all socioeconomic levels, and from various racial groups, including White, Black, Hispanic or Latino, and other mixed racial group. Subjects with IEPs for special services but who attended regular education classes were also

included. Subjects who did not use English proficiently at school, were nonverbal, had any degree of hearing loss, or resided outside the United States were excluded from the standardization studies for each test. Subjects were from all geographic regions of the United States. The sample population reflected the national school population demographics from the 2004 national census for race, gender, age, and educational placement for the item pool and standardization studies.

For both tests, the item pool items were administered to random samples of subjects at yearly age intervals. Subjects included in the item pool studies were not included in the standardization studies.

A team of expert speech-language pathologists determined credit levels for item pool responses during a response analysis session. Items that did not show statistical age progression, showed bias, or were not deemed fair for an ethnic group were eliminated. Item difficulty indexes and item discrimination indexes were computed for each item at each of the yearly age levels. Items retained for the final versions of the test met two empirical criteria:

1. Demonstrate age progression in terms of increasing percents of subjects passing at successive age levels
2. Demonstrate significant discrimination between high and low scorers on the subtest at each age level

The test examiners were speech-language pathologists who held a master's degree or higher from an accredited university.

SLDT-E

Item Pool

1. Four subtests, 68 items.
2. $N = 390$ subjects ages 6 years, 0 months to 11 years, 11 months.
3. Data was gathered at yearly age intervals.

Standardization

1. Four subtests, 48 items.
2. $N = 1104$ subjects ages 6 years, 0 months to 11 years, 11 months.

3. Data was gathered at half-year age intervals. The item pool analysis showed that significant changes in social language development could be shown by grouping subjects in this manner.
4. Test examiners were required to make value judgments regarding the appropriateness of responses and to score them as indicated on the scoring standards provided to them.
5. The final version of the test has four subtests, 12 items per subtest for a total of 48 items.

SLDT-A

Item Pool

1. Five subtests, 89 items.
2. $N = 500$ subjects ages 12 years, 0 months, to 17 years, 11 months.
3. Data was gathered at yearly age intervals.

Standardization

1. Five subtests, 69 items.
2. $N = 834$ subjects ages 12 years, 0 months, to 17 years, 11 months.
3. Data was gathered at half-year age intervals. The item pool analysis showed that significant changes in social language development could be shown by grouping subjects in this manner.
4. Test examiners were required to make value judgments regarding the appropriateness of responses and to score them as indicated on the scoring standards provided to them.
5. The final version of the test has five subsets, 12 items per subtest for a total of a 60 items.

Mean and median raw score values and standard deviations for each subtest and the total test score were computed for both tests. There were no significant gender differences which supported the use of combined male-female norms for the elementary and adolescent tests.

For reporting purposes, three types of scores are used: age equivalents, percentile ranks, and standard scores.

Reliability was established by both the use of test-retest and internal consistency methods. Table 1 represents the internal consistency results

for the SLDT-E, and Table 2 represents the internal consistency results for the SLDT-A.

Empirical validity for each test was established with contrasted groups. Validity was established by comparing the test performances of randomly selected subjects from the sample population with a matched sample of subjects with language disorders and autism spectrum disorders receiving special services. The SLDT-E and the SLDT-A significantly discriminate between these clinical groups at most age levels. The exception is on the SLDT-E for ages 6–0 through 6–5. In this age group, the normative sample and the language-disordered group did not show a significant difference for the total test score.

Construct validity was established with point biserial correlations. Inspection of these correlations revealed highly satisfactory levels of item consistency for both tests (88% for the SLDT-E and 97% for the SLDT-A). The subtest intercorrelations and the correlations of individual subtests with the total test suggest that the subtests do assess separate social language functions but also measure a common general dimension. Overall, internal consistency estimates were satisfactory.

Race/socioeconomic group differences were conducted at the subtest level for both tests. Random samples of White, Black, and Hispanic or Latino student performances at the item level were compared by analyzing the proportion of students passing each item and at the subtest level by:

- Chi-square analyses to determine if significant relations existed between race and test performance
- Two-factor analysis of variance (ANOVA) analyses

In the SLDT-E, there were race differences in only 11% of the total number of the possible statistical tests for race and socioeconomic status (SES) group differences in only 18% of the statistical tests for that factor. In the SLDT-A, there were race and SES group differences in only 5% of the total number of the possible statistical tests for race and SES differences in only 15% of the statistical tests for that factor.

Social Language Development Test, Table 2 Reliability based on item homogeneity: Kuder-Richardson (KR20) coefficients for each task, each subtest, and total test by age

Chronological age	Making inferences			Interpersonal negotiation subtest					Multiple interpretations	Supporting peers	Total test
	Task a	Task b	Making inferences total	Task a	Task b	Task c	Interpersonal negotiation total				
6-0 ... 6-5	.75	.73	.84	.84	.76	.83	.93	.74	.77	.95	
6-6 ... 6-11	.78	.76	.86	.86	.77	.83	.93	.71	.77	.96	
7-0 ... 7-5	.70	.74	.82	.75	.71	.78	.89	.68	.76	.94	
7-6 ... 7-11	.75	.73	.82	.81	.67	.75	.90	.70	.74	.93	
8-0 ... 8-5	.78	.77	.86	.80	.66	.75	.88	.65	.66	.93	
8-6 ... 8-11	.76	.74	.84	.83	.73	.78	.91	.68	.77	.95	
9-0 ... 9-5	.71	.62	.80	.83	.52	.75	.87	.68	.77	.93	
9-6 ... 9-11	.70	.63	.79	.76	.56	.68	.85	.67	.73	.92	
10-0 ... 10-5	.69	.74	.83	.78	.70	.76	.90	.67	.62	.93	
10-6 ... 10-11	.76	.60	.80	.38	.46	.69	.77	.65	.57	.87	
11-0 ... 11-5	.80	.78	.88	.89	.78	.82	.94	.74	.83	.97	
11-6 ... 11-11	.73	.67	.80	.45	.44	.72	.75	.65	.65	.89	
Median KR20	.74	.71	.83	.75	.65	.76	.88	.68	.72	.93	

For both tests, the differences were usually small with most of them in the magnitude of one or two raw scores. Collectively, the results indicate that neither race nor SES group has a major impact on possible race or SES group bias for either the elementary or adolescent test. Further study is warranted however.

Clinical Uses

The results obtained from diagnostic testing should help the examiner to:

1. Identify the student's strengths and weaknesses
2. Make recommendations for additional testing
3. Make well-founded, educationally significant recommendations for remediation
4. Help teachers, parents, guardians, and the student understand the nature of the student's social language functioning
5. Make well-founded recommendations for boosting social success in school and at home

A student's performance on either of these tests may relate to his academic performance and peer interaction. A student may perform poorly on these tests because he has below average vocabulary skills, difficulty recognizing and interpreting facial expressions and body language, does not know the steps involved in processing a photo of someone, etc.

Performance on the individual subtests and total test performance, along with additional diagnostic tests and parent/teacher report, will give the SLP a framework for developing a remediation program that addresses the student's social language weaknesses and builds on the student's strengths.

For each subtest on the SLDT-E and SLDT-A, the authors identified error patterns and, based on those, identified remediation strategies for the SLP. These are described in the examiner's manuals.

As previously stated, these tests do not address all aspects of social language or pragmatic skills. They focus on social interpretation and interaction with peers and/or friends and are the first tests to

have normative data on which to base therapeutic decisions. The authors encourage further research into social language skill development.

Social Learning Disability/Difference

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

[Autism spectrum disorder](#)

Definition

The term social learning disability/differences was coined by Volkmar (2016) as a way to more simply explain the nature of autism/Asperger's disorder/autism spectrum disorder. It was also chosen as a non-prerogative term that readily conveyed way to play problems/differences in social learning in the broader context of learning disabilities. This has some practical advantages in countries like the USA which strongly emphasize inclusion of individuals with learning problems in ongoing community life and occupation.

Terms like learning disability or learning disorder have commonly been used in English-speaking countries for effete to a range of problem in various areas such as reading, writing, math,

spelling, organization (executive functioning), and so forth (O'Brien and Pearson 2004). The literature on these disabilities/differences is relatively large and complex and the ways in which these problems have been defined both diagnostically and legally. It is often the case that a diagnosis of learning disability is made in the context of an individual with average (or even above average) intellectual potential. In the USA Section 504 of the Rehabilitation Act of 1973 had granted certain rights to individuals in occupation and educational (college) settings. This act differs from the Individuals with Disabilities Education Act that applies to children attending schools. Similar regulations exist in Canada and the UK while differing at times in specific definitions employed. The effects of learning disabilities broadly defined can be significant with lowered academic performance, poor self-esteem, and social problems. The term also (implicitly) recognizes the broad range of problem referred to typically as the broader autistic phenotype (Ingersoll et al. 2014).

For autism spectrum disorder, it is increasingly clear, as Kanner himself first suggested (1943) that the marked problems in social engagement, often from the beginning of life, have profound consequences for learning and may result in significant long-term social, communicative, and cognitive problems and additionally may complicate organization of executive functioning skills (NRC 2001; McPartland et al. 2014). There is an increasing large literature noting problems in areas such as joint attention, face perception, and so forth, and it is presumed that these problems pose great challenges for the individual acquiring knowledge in more typical ways (McPartland et al. 2014). Put another way without the "social frame" within which to view the world individuals with social learning differences/disorders may learn idiosyncratic ways often employing unusual strategies such as gestalt learning (Brosnan et al. 2004).

Practical advantages of the term include the focus on the social learning aspects of autism. It also may simplify understanding of lay audiences. As with other learning difficulties/differences, it also emphasizes the importance of inclusion and a commitment to helping individuals with learning differences.

Social Motivation and Friendship Experiences of Autistic Adolescents

Felicity Sedgewick¹ and Elizabeth Pellicano²

¹School of Education, University of Bristol, Bristol, UK

²Macquarie School of Education, Macquarie University, Sydney, NSW, Australia

Definition

Social motivation is defined as the intrinsically rewarding nature of interacting with other people.

Friendships are defined as reciprocal relationships between two people, characterized by

communication over time and a degree of emotional closeness and trust.

We use “identify-first” language (“autistic person”) rather than person-first language (‘person with autism’), because it is the preferred term of autistic activists (Sinclair 1999) and many autistic people and their families (Kenny et al. 2016) and is less associated with stigma (Gernsbacher 2017).

Historical Background

Having stable reciprocal friendships is held to be a key indicator of a “good adult outcome” (Goldfarb et al. 1976). It is unsurprising, then, that many adolescents and adults diagnosed with autism – defined in part by “deficits in developing, maintaining, and understanding relationships” (American Psychiatric Association 2013) – rarely achieve such good outcomes, as defined in this way. Long-term longitudinal studies have found that autistic people have few, if any, friends, are less likely to be married or in a long-term romantic relationship (Howlin 2000; Howlin et al. 2013), and are more likely to rely on their parents for social support than on same-age peers or colleagues (Howlin et al. 2004) than their neurotypical counterparts. These findings have fueled a wealth of research on the social connections of autistic children and young people (review: Petrina et al. 2014) and generated numerous interventions and supports designed to help autistic children and young people develop and maintain long-lasting friendships with others (review: Chang and Locke 2016).

There is increasing recognition, however, that traditional, normative markers of what a successful (social) outcome is for an autistic person all too often have been derived on the basis of *non-autistic* researchers and clinicians’ perspectives, rather than on the views of young autistic people themselves (Cribb et al. 2019; Ruble and Dalrymple 1996). In this review, we provide an overview of research, which focuses on young autistic people’s own subjective experiences of their friendships, identifies key factors that contribute to variation in those definitions and outcomes,

and seeks to develop effective interventions to support them in achieving their goals.

Current Knowledge

Friendships on the Autism Spectrum

It has been repeatedly demonstrated that young autistic people have fewer friendships (Bauminger and Shulman 2003) and higher levels of loneliness (Bauminger and Kasari 2000), and experience greater social exclusion than both neurotypical young people and those with other neurodevelopmental conditions (Kasari, Locke, Gulsrud and Rotheram-Fuller 2011; Locke, Ishijima, Kasari, and London 2010; Rowley et al. 2012). Difficulties with developing friendships and social relationships have often been attributed to “diminished social motivation” (Chevallier et al. 2012) suggesting that autistic people cannot, and do not *want*, to form friendships (for critical review, see Jaswal and Akhtar 2019). Yet, anecdotal reports combined with long-standing empirical work suggest, however, that this is not always, or even usually, the case.

Research has demonstrated that autistic people are interested in forming secure and supportive friendships and are emotionally invested in the friendships they have (Calder et al. 2013; Sumiya et al. 2018). They report having friends and best friends (Mendelson et al. 2016; Sedgewick et al. 2016) and have a desire to play with, and chat to, their non-autistic peers (Travis et al. 2001). Autistic children tend to have fewer friends than non-autistic children, see those friends less often, and tend to focus on shared activities rather than emotional sharing – but are highly satisfied with their friendships regardless of these differences (Petrina et al. 2014). This is the case regardless of whether their nominated friend is also autistic, and the non-autistic friends of autistic children are just as happy with the friendship as the autistic partner (Petrina et al. 2017). Importantly, a recent study has shown that mental age-matched autistic and non-autistic children (estimated average 10 years old) had similar expectations of their friendships (Bottema-Beutel et al. 2018).

The extent and nature of young autistic people's friendships could be influenced by several factors, including (1) homophily, (2) others' acceptance and inclusion of young autistic people, (3) an individual's motivation to make and keep friends, and (4) gender.

Homophily. Homophily – similar interests, beliefs, and attributes – is a strong element in the friendships of non-autistic young people (Shrum et al. 1988), and the same is true for young autistic people. Recent research has shown that they take similar features into consideration when making and maintaining friendships as their non-autistic counterparts, such as shared interests and wanting similar types and levels of interaction (Finke et al. 2019).

Research has also demonstrated that young autistic people who are involved in extra-curricular activities like sports and hobby clubs have more friends than those who do not take part in these activities, often facilitated by the shared interest (Dovgan and Mazurek 2019). Shared interests can also help to build social skills, thereby improving social relationships (Nabors et al. 2017). These shared interests do not have to be in-person activities. Many autistic people make genuine friendships online, for example, through gaming or social media (Brownlow et al. 2015; Ringland et al. 2016). Online interactions require less decoding of complex social information, such as tone of voice and body language, and come with a ready-made set of emotional indicators (emojis) and non-verbal reactions (e.g., gifs, memes) with recognized meanings. Adults on the autism spectrum have expressed that communicating online is good for them as it gives them time to plan what they want to say and because it removes the challenges of face-to-face talking (Benford and Standen 2009; Burke et al. 2010). Social media use has been shown to be associated with higher friendship quality for autistic adolescents, though high levels of anxiety had similar negative effects on offline and online friendships (van Schalkwyk et al. 2017). That online friendships should be considered a central part of our definition of friendship is important in recognizing the reality of social engagement in the modern world.

Acceptance and Inclusion. Another aspect which has been found to be key in building positive friendships for young autistic people is acceptance. Research in this area is relatively new, although there is a multitude of first-person accounts of the stigma experienced by autistic people and the difference an accepting community can make to wellbeing and quality of life.

Among autistic people, greater acceptance of their autism and associated needs is linked to better relationships, better mental health, and greater life satisfaction (Cage et al. 2018). Positive self-perceptions also mediate the relationship between increased self-esteem and better mental health (Cooper et al. 2017). Young autistic people are often anxious about “getting things wrong” socially, so finding friends who are accepting of their differences and allow them to be their authentic selves is important, and these friendships are stronger than relationships where they feel they must pretend not to be autistic (Sosnowy et al. 2019). Indeed, positive correlations have been found between good peer interactions and friendships and increased self-esteem among young autistic people (Johnson 2019). This research highlights the importance of young autistic people building the friendships they want to have, rather than being encouraged to have friendships like those of young people who are not on the autism spectrum.

Motivation to make and keep friends. The well-known social motivation theory posits that autistic people have lower levels of social motivation, such that they find social interaction less intrinsically rewarding and do not seek out relationships (Chevallier et al. 2012). Recent work thoroughly critiques this conception of autistic people's social lives (Jaswal and Akhtar 2019). Indeed, in a study of autistic and non-autistic children's social networks, Calder et al. (2013) found that it was autistic children's social motivation that appeared to account for the significant variation in the nature and extent of their friendships. While some young autistic people desperately wanted friends, others had limited social connections but preferred things this way: “I am happy with my life right now. I am not friendly and talkative, but

I am not not friendly. I am somewhere in the middle” (p. 12).

One potential source of individual differences in young autistic people’s motivation for making and keeping friends is gender. Just as there are recognized gender differences in the nature and extent of friendships among people who are not autistic (Aukett et al. 1988; Caldwell and Peplau 1982; De Goede et al. 2009), there is growing evidence for gender differences in the friendships, social skills, and social motivation of young autistic people. Research on autistic friendships and social relationships has almost exclusively focused on male participants, largely based around the historical assumption that autism is a mostly male condition and/or the belief that those few girls who received a diagnosis were so rare as to be unrepresentative and not worth including (Gould and Ashton-Smith 2011; Haney 2016). As there is increased recognition of the differences between males and females on the autism spectrum (Lai et al. 2015), understanding the differences in their friendships, and what causes these differences, is important for being able to support young autistic people to have positive social relationships.

Autistic girls are more likely to have apparently typical social development (Bauminger et al. 2010) than autistic boys. This is in part because autistic girls tend to be more motivated toward, and skilled at, imitating the social behaviors of their peers, such as cooperative and pretend play (Kopp and Gillberg 2011). Autistic girls engage in complex imitation (Hiller et al. 2014), have language skills similar to those of non-autistic female peers (Goddard et al. 2014; Kauschke et al. 2016), and are more socially cooperative (Mandy et al. 2012) than autistic boys. Potentially driving these differences, autistic girls have consistently been found to have higher levels of social reciprocity and social motivation than autistic boys (Head et al. 2014; Mandic-Maravic et al. 2015; Sedgewick et al. 2016, 2018).

These skills, combined with higher levels of “camouflaging” behaviors aimed at helping autistic girls to hide their social challenges and appear “normal” so they can try to fit in (Dean et al. 2017;

Hull et al. 2017; Milner et al. 2019), mean that autistic girls are likely to have very different social experiences to autistic boys. The social isolation of autistic girls is often less obvious, being more akin to neglect than active rejection (Dean et al. 2014) and means that parents and teachers may not notice and intervene to help them make friends.

Gender Differences. There are significant differences in the ways in which adolescent autistic boys and girls spend time with their friends, despite spending similar amounts of time socializing overall (Kuo et al. 2013). Autistic boys tended to play games with their friends, whereas autistic girls were more likely to chat with theirs. Another study found that autistic girls aged 10–16 years scored significantly higher on the Friendship Questionnaire – with higher scores representing better friendships – than autistic boys and, furthermore, scored similarly to boys who were *not* autistic (Head et al. 2014). This finding was supported by parental reports of the children’s relationships, suggesting that autistic girls have better social skills and higher social motivation than autistic boys.

Research suggests that, as girls face similar expectations regardless of diagnostic status, being female may be more important in determining social experiences than being autistic, and this needs to be considered when supporting autistic girls (Carpenter et al. 2019). For example, studies of social motivation and friendships among autistic adolescents in both special (Sedgewick et al. 2016) and mainstream (Sedgewick et al. 2018) education settings found gender differences consistent with those of non-autistic adolescents. Autistic girls rated their best friendships as closer and more supportive than autistic boys, at similar levels to non-autistic girls. Those best friendships were also characterized by similar behaviors to non-autistic girls, such as emotional sharing and talking about other people, rather than being focused on shared actions or objects (i.e., games or lessons).

Where there were important differences between autistic and non-autistic girls was in the form their friendships took. While non-autistic girls tended to have several best friends plus a

wider group of friends and acquaintances, autistic girls had one or two best friends without a wider group, and the best friendships of autistic girls were very intense and could be an all-consuming preoccupation. Nevertheless, autistic girls often spent time with their friends in the same ways as non-autistic girls, such as chatting and going to the cinema, and saw their friendships as just as important and positive as non-autistic girls did.

Supporting Friendships

The research reviewed above demonstrates that a range of factors influence the friendship experiences of young autistic people. Any interventions or strategies that seek to support the formation and maintenance of positive friendships for young autistic people must consider shared interests, non-autistic peers' attitudes toward the young autistic person, and young people's preferences for making and keeping friends – allowing them to form their own vision of a “good” social life. One key area where specific support is likely to be needed is in navigating the negative aspects of social relationships, both bullying and conflict within friendships, which are all too common for young autistic people.

Young autistic people are more likely to be bullied than their peers due to their social vulnerabilities (Cappadocia et al. 2012; Sofronoff et al. 2011), with up to 94% of young autistic people reporting being bullied (Hebron and Humphrey 2014; van Roekel et al. 2010). Being bullied is associated with being more likely to have mental health issues in young autistic people, though those with good friends and higher self-esteem are somewhat protected (Cook et al. 2016).

Although there is a wealth of work on bullying of young autistic people (for review, see Hong and Espelage 2012), little research has been conducted on the impact of conflict *within* their friendships and peer relationships. These behaviors can have negative impacts similar to those of more overt bullying but, critically, take place within relationships typically categorized as “friendships.” This categorical (friends, who are usually nice to you) and behavioral (someone being unpleasant or bullying) mismatch can lead to difficulties for any adolescent who must try to make space for mean

behaviors within the concept of a “friend” but may be especially puzzling for teenagers on the autism spectrum. Indeed, autistic adolescents can often have a “fixed” and “active” definition of friendship, focused on doing things with someone – “someone you hang out with” (Bauminger and Kasari 2000; Calder et al. 2013) – rather than emotional closeness, which may leave autistic adolescents vulnerable to social manipulation.

Importantly, this fixed definition of friendship can also lead to fixed ideas about what represents a breach of that friendship. One study showed that young autistic people view “betrayal” as the most severe transgression in a friendship (Bottema-Beutel et al. 2018). The perspective-taking difficulties often experienced by young autistic people might mean that they can misinterpret the actions of others as a transgression when they were not intended as such (van Roekel et al. 2010). They may then react more easily (Mazefsky et al. 2013) and in a more emotionally extreme manner than non-autistic young people would (Gomez and Baird 2005; Volker et al. 2010). They are also less likely to forgive a friend who upsets them (Rogé and Mullet 2011) due to a sense of having been done an injustice. This emotional reaction, however, is likely to result in further teasing from peers rather than reducing the bullying.

Just as young autistic people generally are more likely to be bullied than non-autistic young people, autistic girls are more likely to be bullied than autistic boys (Sedgewick et al. 2018). The challenges of friendship formation and maintenance may be especially significant for autistic girls, who are more likely to experience relational conflict than autistic boys, just as non-autistic girls experience more relational conflict than non-autistic boys (Bowie 2007). In light of these gender differences, research has started to explore how autistic girls experience and manage relational conflict. Several studies have found that autistic girls experience high levels of this conflict and often fall out with friends as a result of it (Milner et al. 2019; Sedgewick et al. 2018). One study found that autistic girls are more likely to have an “all or nothing” response to conflict with a friend, seeing it either as entirely their fault and therefore entirely their responsibility to ‘fix’ or as

entirely the other person's fault and entirely for them to resolve (Sedgewick et al. 2018). Other work has shown that autistic girls do have conflict resolution strategies but can struggle to predict the expectations of their peers and so face difficulties effectively deploying these approaches (Vine Foggo and Webster 2017). Indeed, research has shown that difficulties with developing and using social problem-solving strategies are common for young autistic people (Hochhauser et al. 2015), even when they are highly motivated to repair the damage and want to maintain the friendship.

Future Directions

There is a huge amount still to learn about friendships among young autistic people. There is a need for future research to examine the experiences of those young people who are non-binary and transgender; on the ways that social relationships change over time, especially during times of life transition; on the reciprocal influences of mental health and friendships on the well-being of young autistic people; and on the differences between mixed autistic/non-autistic and non-mixed friendships.

The friendships young autistic people choose to make may not look exactly like those of non-autistic young people. But they are valid and genuine, and appear to have similar beneficial long-term impacts as all friendships. Understanding that these friendships are possible for young autistic people, and that they can enjoy these friendships on their own terms, is a critically important message, which should be shared with young people, their families, and the people supporting them.

See Also

There are a range of programs designed to support social skills and relationships among autistic young people. Some examples include:

The Program for the Education and Enrichment of Relational Skills (PEERS; Laugeson et al. 2014) – a 16-week program of lesson plans to help autistic

young people develop social skills and practice social interaction

Social Stories (Gray 1994) – a manualized approach to designing individualized stories to help autistic young people predict and practice social interactions
The Hidden Curriculum (Myles, Trautman and Schelvan 2004) – a book that gives practical tips and tutorials for teachers and parents to support autistic young people in learning unwritten social rules

The Secret Agent Society (Beaumont et al. 2015) – a social-emotional skills training program for school-aged autistic children that includes child group sessions, parent workshops, and teacher tip sheets, home missions, using a multilevel computer game and a system to reward and monitor progress at home and school

The Transporters (Golan et al. 2010) – an animated series which aims to teach autistic young children about reading facial expressions and emotions displayed on the face

Girls Night Out (Jamison and Schuttler 2017) – a social skills and self-care program designed with autistic adolescent girls in mind, aimed at helping them understand and engage with their peers more successfully

Social Pragmatic Communication Disorder

► Autism: Social Communication Disorder

Social Responsiveness Scale

John N. Constantino
Department of Psychiatry, Washington University
School of Medicine, St. Louis, MO, USA

Synonyms

SRS

Abbreviations

AUC	Area under curve
ADHD	Attention deficit hyperactivity disorder
ADI-r	Autism diagnostic interview-revised
ADOS	Autism diagnostic observation scale
ASD	Autism spectrum disorder
BPVS	British picture vocabulary scale
CBCL	Child behavior checklist
CCC	Children’s communication checklist
OCD	Obsessive compulsive disorder
PDD-NOS	Pervasive developmental disorders-not otherwise specified

ROC	Receiver operating characteristics
SCDC	Social and communication disorders checklist
SCQ	Social communication questionnaire
VABS	Vineland adaptive behavior scales

Description

The Social Responsiveness Scale (SRS) is a 65-item rating scale that measures the severity of autistic symptomatology as a quantitative trait, among children clinically affected by autism spectrum conditions as well as among children in the general population. It is particularly useful for characterizing milder autistic syndromes that lie at the boundary between the normal population distribution and clinical-level affectation. The SRS can be completed by a parent, a teacher, a spouse (in the case of the adult version of the SRS), or another adult informant. The validity of self-report is still under study. The SRS involves ratings of children in their natural social contexts and reflects what has been consistently observed over weeks or months of time rather than in a single clinical or laboratory observation. In this way, it capitalizes on both direct observation and on the accumulated history of behaviors observed by the informant over time. The SRS generates quantitative scores for the severity of autistic traits and symptoms, and distinguishes Autism Spectrum Disorder (ASD) from other psychiatric conditions (Constantino et al. 2000). Norms have been published by gender and rater type (parent versus teacher) in order to standardize ratings, which otherwise differ as a function of these parameters. SRS scores are highly heritable (Constantino and Todd 2003), stable over time (Constantino et al. 2009), exhibit high inter-rater reliability (Constantino et al. 2007a), are continuously distributed in the general population (Constantino and Todd 2003), are nonsignificantly correlated with IQ among children representing the normal range of IQ in the general population (Constantino et al. 2007a), and exhibit a unitary factor structure (Constantino et al. 2004), which supports the use of a single index score as a quantitative measure of autistic severity. SRS scores greater than 75 *T* (98.8th percentile)

indicate a level of autistic social impairment that is generally highly clinically significant.

Historical Background

Over the course of some 25 studies involving over 10,000 individuals (including Constantino et al. 2006, 2007a, 2007b, 2009; Constantino et al. 2003b; Gruber 2005; Constantino et al. 2003b; Constantino and Todd 2000; Lee et al. 2010; Levitt and Campbell 2009; Pine et al. 2006; Virkud et al. 2009), research involving the SRS has yielded information about the distribution of autistic traits and symptoms in children and families affected by autism, as well as children and families in the general population. Complementary research involving an array of other quantitative rating scales has converged with findings from studies involving the SRS in demonstrating that quantitative autistic traits *exhibit a continuous distribution in nature* (from very mild to very severe, see Fig. 1 panel A below) and are substantially heritable (estimates on the order of 0.60–0.80). The traits and symptoms captured by the SRS are extremely stable over time (5-year test-retest correlations on the order of 0.60–0.70 in clinical samples and 0.70–0.80 in nonclinical populations, as depicted in panel B below), yet capable of fluctuating within individuals over time and in response to intervention. The SRS is currently in use in a broad range of settings, including schools, clinical services, and research programs. It offers the capability of feasible and reliable quantitative characterization of core components of the autistic syndrome across informants and across environmental contexts, and has been translated into over 20 foreign languages at the time of this writing.

Psychometric Data

Each version of the SRS can be completed in 15 min and generates both scale scores for specific symptom domains relevant to the characterization and treatment of autistic syndromes, as well as a singular total score for autistic social impairment,

empirically validated via factor, cluster, and latent class analysis (Constantino et al. 2004, 2007a). Higher total scores on the SRS indicate greater severity of social impairment; and inter-rater reliability is high (parent-teacher correlation 0.72, $n = 1,200$). The SRS exhibits nonsignificant correlations with IQ, and substantial agreement with the Autism Diagnostic Interview (ADI-r) and the Autism Diagnostic Observation Scale (ADOS) (Constantino et al. 2003, Constantino et al. 2004, Constantino et al. 2007a; Lee et al. 2010). Parent-report scores on the SRS distinguish children with ASDs (including Autistic Disorder, Asperger Disorder, and Pervasive Developmental Disorders [PDD-NOS]) from those with other child psychiatric conditions (Constantino et al. 2004; Constantino et al. 2000; Constantino et al. 2007b; Constantino and Gruber 2005). Autistic traits and symptoms measured by the SRS are continuously distributed not only in clinical populations but in the general population (Constantino and Todd 2003). Furthermore, traits measured by the SRS aggregate in the male first-degree relatives of subjects with ASD in multiple-incidence families (Constantino et al. 2006; Virkud et al. 2009). In addition, there is evidence from molecular genetic studies that SRS scores map to specific autism susceptibility loci (Duvall et al. 2007; Levitt and Campbell 2009; Coon et al. 2010).

Internal Consistency

Internal consistency is a form of reliability that can be estimated from a single administration. Studies using the SRS have reported very high estimates. The earliest study on the SRS (Constantino et al. 2000) assessed internal consistency in regular education children aged 4–7 years ($N = 197$). An alpha .97 was obtained. In a report on a clinical sample using the German translation, Bolte et al. (2011) obtained an alpha .94 in a mixed clinical group ($N = 255$) and alpha .96 in an ASD group ($N = 148$).

Retest Reliability/Temporal Stability Construct Validity

Retest reliability and temporal stability are closely related psychometric constructs. While the actual

study principle is the same – an individual is asked to fill in an instrument twice so that results can be compared after time delay – the meaning of the result changes substantially when the two procedures are separated over increasingly long time periods. When the interval is short, say a few weeks to a few months, the study is said to address test-retest reliability and findings are attributed narrowly to the reliability of the instrument.

When the interval is longer however, say on the order of 6 months to several years, then the study is said to address temporal stability and the results are attributed to the validity of the underlying construct (autism in the case of the SRS) and of the instrument.

Research interest has focused on longer intervals in clinical populations. It is a testimony to both the high validity of the autism construct and

Social Responsiveness Scale, Fig. 1 *School-age SRS studies: (a) General population distribution (b) 5-year Stability.* (Constantino et al. 2009)

to the SRS in measuring that construct that correlations have been very high. Constantino et al. (2000) reported on a clinical group ($N = 30$) with a retest interval averaging 137 days and found a correlation $r = .88$. Bolte et al. (2009) assessed a clinical group ($N = 49$), with a 3–6 month retest interval and found a retest correlation of $r = .95$ was obtained. Constantino et al. (2009) tested 95 male twin pairs ASD affected and 95 males typically developing (total $N = 285$) longitudinally over a 5-year period and found that retest correlations maintained around $r = .90$ in both groups, as shown in Fig. 1 Panel B.

In general, the reliability of an instrument is seen as a strong constraint on its validity. Thus, the evidence of longer interval construct stability above, with correlations on the order of 0.80–0.90, tends to obviate the need to put resources into documenting short interval retest reliability. Bolte et al. (2008) did evaluate retest reliability in conjunction with the development of the German edition, but only in the normative group. With a retest interval ranging from 3 weeks to 4 months, they found retest reliability was $r = .80$ for mothers and $r = .72$ for fathers.

Inter-rater Reliability/Convergent Validity

Inter-rater report comparisons serve two functions. In a narrow sense they are an aspect of reliability, since they involve applying the same items to the same child. Yet inter-rater comparisons also go beyond that to provide a broader aspect of validity, since they involve passing the items through different experience bases. Thus, mother and father, even while living in the same home and sharing many family experiences, do each have separate personal experiences with a child and, moreover, a unique prior personal history that can influence how each will interpret the meaning of the 65 test items. And this sense of difference in background, experience, and perspective expands even more when a parent report is compared to that of a teacher; for one a teacher and a parent have virtually no overlapping observations of a child's behavior and for another a teacher, while seeing the child in a more limited setting than the parent, can draw on professional training and direct experience with scores and

even hundreds of other children when judging the child's behavior.

Despite these differences in perspective, studies reporting on different observers have found highly concordant reports. With regard to mother-father inter-rater agreement, Constantino et al. (2003a) collected mother and father reports in a sample of ASD-diagnosed individuals ($N = 61$). They found mother-father reports correlated $r = .91$. Bolte et al. (2008), using the German edition, reported on 527 mixed clinical cases (160 with ASDs) and also found mother-father reports correlated $r = .91$. In the normative sample, Bolte et al. (2009) obtained a mother-father correlation $r = .61$. Prior comments regarding results in normative or other less-affected groups apply again here.

Parent reports have also been compared to teacher reports in clinical samples. Regarding parent-teacher comparisons, Constantino et al. (2003a) found mother-teacher reports correlating $r = .82$ and father-teacher reports correlating $r = .75$ (both $N = 61$). In a later study Constantino et al. (2007a) compared teacher- and parent-report SRS scores in a larger sample ($N = 577$) of clinically referred children and found parent-teacher reports correlated $r = .72$. As noted in the introductory comments, differences in experience bases are much larger between teachers and parents than between parents. These finding on parent-teacher comparisons are also highly indicative of strong reliability and validity.

Comparisons with Other Instruments: Concurrent Validation

Two broad issues can be addressed from reports where the SRS has been used with other instruments. Of these, *convergent validity* compares the instrument to others that have the same focal purpose. For the SRS, this involves comparisons with other instruments that are designed to evaluate symptoms and behaviors on the Autism Spectrum. In these comparisons, higher correlations are desirable. In contrast, *divergent/discriminant validity* addresses the instrument's performance in contexts where a broader variety of symptoms and behavior problems need to be addressed. For the SRS, this could involve comparison to

instruments that assess other commonly identified psychological disorders and behavioral problems – for example, behavioral expressions of internalizing problems of anxiety, depression, and Obsessive Compulsive Disorder (OCD) or behavioral expressions of externalizing problems such as Attention Deficit Hyperactivity Disorder (ADHD), conduct disorders, and Bipolar disorder – or those that assess less specifically linked problems such as developmental delay. In these comparisons, moderate- to lower- or even zero-order correlations are desirable, demonstrating that the SRS explains variance that is unique to the social behavior associated with ASDs and not strongly overlapping with that due to behavioral difficulties associated with other disorders and identified by other instruments.

Convergent Validity

Parent and Teacher Report Behavior Assessments. Comparison with other ASD-directed measures have largely involved instruments using a similar approach to assessment: multiple item objective questionnaires with a multipoint Likert-scale or a true-false response format that is completed by informants familiar with the child's behavior in natural living contexts such as parents and teachers. Good agreement has been reported with the several instruments that have been investigated.

The most widely investigated comparison has been with the Social Communication Questionnaire (SCQ; Rutter et al. 2003), an instrument that uses a true-false response format with 40 items derived from the ADI-r. Findings with the SRS have been relatively consistent. In studies with mixed clinical samples as cited earlier, Charman et al. (2007) report a correlation $r = .68$ ($n = 119$); Bolte et al. (2008) report $r = .58$ ($n = 107$). In addition, also in a mixed clinical sample, (Pine et al. 2008) found $r = .65$ ($n = 352$) and in a small sample of children affected by epilepsy Granader et al. (2010) report $r = .61$ ($n = 21$). A slightly lower value was reported by Bolte et al. (2011), $r = .50$ ($n = 480$), in a sample that included typically developing as well as clinical subjects.

There have also been several studies correlating SRS scores with those from the Children's

Communication Checklist (CCC; Bishop 1998), a 70-item instrument with a Likert scale response format. Pine et al. (2008) reports correlations or $r = -.49$ and $-.72$ with the two ASD-focused (and positively valanced) subscales. Similarly, Charman et al. (2007) report a SRS to CCC correlation $r = -.75$.

The SRS has also been compared to the Social and Communication Disorders Checklist (SCDC, (Skuse et al. 2005)) a brief, 12-item scale using a 3-point Likert scale response format. Using German translations, Bolte et al. (2011) found the instruments moderately correlated $r = .49$.

The ADI-r and the ADOS. The SRS has also been compared to instruments that are less similar in design, in particular the Autism Diagnostic Interview, revised (► ADI-r; Lord et al. 1994) and the Autism Diagnostic Observation Schedule (► ADOS; Lord et al. 2000).

The design characteristics of these instruments are quite different from that of the SRS and other behavioral parent and teacher reports cited in the previous section. The ADI-r is a long structured psychiatric interview from which a subset of questions are selected and coded; the ADOS is a structured observation of behavior conducted by a trained professional under standard conditions from which pre-identified behavior is identified and coded. Both instruments were designed to facilitate categorical, diagnostic decision making and, consequently, do not produce the same kind of dimensional results produced by the objective questionnaires. It has long been recognized that differences in method tend to produce evidence of validity at lower levels of correlation (e.g., Campbell and Fiske 1959). Given the differences, results provided clear support for the validity of the SRS.

ADI-r results include “domain scores,” sums of coded item subsets. Constantino et al. (2003a) reported an early investigation of SRS validity, comparing SRS to ADI-r lifetime scores in a sample ASD-diagnosed individuals ($N = 61$). We note that ADI-r domain scores characterize level of severity around the age of 4 years, at a relative peak in manifestations of autistic symptomatology from the standpoint of developmental history. Despite this fundamental difference between the

SRS (which measures current dysfunction) and the ADI-r (which indexes historic symptomatology in early childhood), correlations between parent-report SRS scores and ADI-r domain scores ranged from .65 to .77 for mother reports, from .52 to .70 for teacher reports, and from .60 to .74 for father reports. In a subsequent report on a larger sample, somewhat lower, though highly statistically significant correlations were reported between SRS Parent reports and ADI-r domain scores (range of $r = .31-.36$) and SRS Teacher reports (range of $r = .26-.40$) (Constantino et al. 2007a). These correlations were on the order of what was observed for correlations between ADI-r and ADOS domain scores. In the study associated with the development of the German edition, Bolte et al. (2008) collected 133 clinical cases and report more specifically on parent reports for the separate domains: Social Interaction Domain score $r = .46$, Communication Domain Score $r = .40$, Stereotypic Behavior Domain score $r = .38$. Charman et al. (2007) used an ADI-r results that combined scores across domains and found a correlation $r = .59$. As noted in the introductory paragraph, the ADI-r was designed to facilitate categorical analyses and its brief domain scores do not provide a strong basis for correlational analyses, for example, Bolte et al. (2009) used standard adjustments to compensate for attenuated ranges in short scales. The relatively stronger finding in the Charman et al. (2007) study may in part reflect the combination of domains into a single, more dimensionalized score.

The same sets of investigators produced parallel findings on comparisons to the ADOS. Constantino et al. (2007a) found ADOS domain scores correlated with SRS Parent reports (range of $r = .37$ to $.58$) and SRS Teacher reports (range of $r = .15-.43$). The Bolte et al. (2008) study reports Communications/Social Deficits score $r = .35$. In a subsequent study Bolte et al. (2011) found correlations in the $r = .32-.35$ range with the ADOS Domain scores. Again, using a single combined domain score, Charman et al. (2007) found an SRS to ADOS correlation $r = .48$. The earlier comments regarding brief domain scores

and Charman et al.'s use of a combined domain score also apply here.

Divergent/Discriminant Validity

The task of differentiating diagnostic groups is addressed by studies cited in a later section. This section provides a more general sense of overall validity from comparing correlations with different instruments and their scales. The comparison scales reported here are directed at a wider variety of mental health problems and diagnoses, some of which may have overlapping symptoms with ASD and others thought or known to have no systematic relation to ASDs. Reported correlations will reflect a validation of the SRS by showing moderate- to low- or zero-order correlations.

As noted earlier, differences in methods can have an impact on correlational evidence (e.g., Campbell and Fiske 1959). Most of the reports in the following discussion involve parent and teacher behavioral reports, similar in design to convergent measures like the SCQ, CCC, and SCDC. The appropriate comparison in this section is with those reported on the parent and teacher report behavioral measures in the previous section.

Studies using the Child Behavior Checklist (CBCL; [Achenbach and Ruffle 2000]) support the view that the SRS is more sensitive to behaviors that can sometimes be associated with ASD-related problems, less sensitive to behavior seldom seen in ASDs, and – perhaps most critically – sufficiently independent of the CBCL to indicate sensitivity to behavioral problems not assessed by the CBCL. Two studies report correlations between the SRS and CBCL in clinical samples, with Constantino et al. (2000) reporting on 84 clinical cases and Bolte et al. (2008) reporting on 119 clinical cases from the German validation studies. Despite the differences in location and language, the findings were quite parallel. Both studies found moderate correlations for the SRS with CBCL subscales that have some overlap with the kinds of symptoms seen with ASDs: Social Problems, Thought Problems, and Attention Problems (correlations range $r = .48$ to $.64$). As expected, results were somewhat mixed but

generally lower for correlation with CBCL subscales directed at less related behavior: Withdrawn, Delinquent Behavior, and Aggressive Behavior (correlations range $r = .34-.54$). Both studies found zero-order correlations for the SRS with the CBCL Somatic Complaints subscale ($r = .11$ and $.12$ ns). In another study involving a general population twin sample, Constantino et al. (2003b) examined overlap in the constructs captured by the scales, suggesting about 16% total shared variance.

Using the Vineland Adaptive Behavior Scales (VABS; Sparrow et al. 1984) studies have reported on the relation of development to SRS scores. Charman et al. (2007) report a correlation of $-.44$ for the positively valenced composite VABS scores with the SRS and Bolte et al. (2008) found a correlation $r = -.36$ for the composite correlations ranging from $-.34$ to $-.43$ for the subscales. This level of correlation appears reasonable for a developmental disorder like ASD. Regarding narrower cognitive ability, Charman et al. (2007) reported no significant correlation of the SRS to the British Picture Vocabulary Scale (BPVS; Dunn et al. 1997).

Clinical Uses

The first question for a clinical assessment is whether affected individuals show scores elevated enough for the assessment to have clinical utility. Independent reports providing information on both typically developing children with those diagnosed as autistic have consistently shown a statistically significant and clinically meaningful separation. Children not affected by ASD or any other disorder are typically reported to have SRS Total Scores in the narrow range from 0 to 35. This is true in studies where children have been drawn to be representative of typically developing populations (Bolte et al. 2008, 2011; Coon et al. 2010) and in studies where matched controls have been drawn (Reiersen et al. 2007; Pine et al. 2008). In contrast, results for groups of children with PDD-NOS, ASD, or autistic disorder find SRS Total Score group means in the range

86–116 (Charman et al. 2007; Constantino et al. 2000; Coon et al. 2010; Kalb et al. 2010). Even given the rather large standard deviations reported for autistic groups (ranging 27–33), the findings indicate a separation of two standard deviations or more. These differences are substantial and have a clear practical utility.

Clear and useful separation can also be seen when contrasting autism with other non-autistic diagnoses. Studies that have presented SRS scores for mixed or specific non-ASD diagnosis clinical samples have reported group SRS Total Score means in the range 40–75, that is, consistently higher than those reported for typically developing groups and lower than those reported for autism-affected groups (Bolte et al. 2008, 2011; Charman et al. 2007; Constantino et al. 2000; Pine et al. 2008; Puleo and Kendall 2011; Reiersen et al. 2007; Towbin et al. 2005). It must be noted that studies will produce different results depending on the specific symptoms associated with the contrast diagnosis and on the severity of clinically affected subjects who are ascertained or recruited.

Screening and Receiver Operating Characteristics (ROC) Reports

The SRS has had a number of clinical applications: qualifying subjects for research studies, providing support for clinical diagnoses, assessment of treatment effects, etc. Wide international concern about autism, however, has also led to an interest in developing and applying screening tools, and the SRS has been studied for this purpose. These studies evaluate an instrument's sensitivity (the proportion of actually affected individuals who are correctly identified) and specificity (the proportion of nonaffected individuals who are correctly identified). In general, there is a trade-off so that increasing specificity degrades sensitivity and vice versa.

The studies reported here reflect the complexity of the screening task (e.g., differing contrast diagnoses, population pools, comparison instruments, and cut points that may favor sensitivity in some cases and specificity in others). Even with the variation, however, the findings to be reported

indicate that the SRS has a useful power to properly identify affected children and to accurately discriminate children with ASD conditions from typically developing children and also from those with varied non-ASD disorders. For a psychiatric sample of 133 children with ASD diagnoses and 126 mixed non-ASD diagnoses (sample described in Constantino et al. (2004)), a ROC analysis was reported. With the standard recommended research cutoff of 75, sensitivity was reported as .85 and specificity as .75. Charman et al. (2007) reported on a sample of children previously identified with developmental or special education risk factors, and contrasted 49 children with confirmed ASD diagnoses with 70 children with confirmed non-ASD diagnoses. Under these conditions, Area Under Curve (AUC) was .77, sensitivity was .78, and specificity was .67.

A larger and more diverse study by using the German translation involved a sample of 480 children, including 148 with ASD diagnoses, 255 with non-ASD clinical diagnoses, and 77 typically developing children (Bolte et al. 2011). Results were reported based on the recommended research cutoff for the SRS of 75 that was used in the prior two reports. Contrasting ASD cases with typically developing children they report $AUC = .98$ with sensitivity = .80, specificity = 1.0. Contrasting ASD cases with the non-ASD clinical group, they report $AUC = .81$ with sensitivity = .80, specificity = .69. Contrasting ASD with a clinical sub-sample of ADHD affected children, they report $AUC = .86$ with sensitivity = .80, specificity = .78. And finally, contrasting ASD with a clinical sub-sample of children with anxiety diagnoses, they report $AUC = .82$ with sensitivity = .81, specificity = .74.

The findings across the three studies and groups are fairly consistent with regard to sensitivity, ranging from .78 to .85 and clustering around .80. With regard to specificity, findings are more varied and depend on the nature of the contrast group, ranging from .69 to 1.0, with perhaps .75 as an adequate single estimate in clinical settings where there are mixed diagnoses in the contrast group. Co-equal high rates, as seen for the SRS, are generally desirable, but there can be applications where favoring one or the other

many be preferred, for example, an instrument with higher sensitivity for use in early, broad population studies or one with higher specificity for use in aiding differential clinical diagnosis. The SRS is highly versatile in this sense; given the fact that it is fundamentally a quantitative trait measure, users can adjust the cutoff values used for screening to optimize sensitivity or positive predictive value.

The results above are reported on the conventional procedure, where a single administration of an instrument is used to identify children with potential problems. The SRS has two features that make it relatively easy to add to screening power. As a behavioral report, it does not require clinician time to conduct the assessment and as a report with several forms, it is relatively easy to collect more than one score on a child, for example, a parent and a teacher or a mother and a father. Taking advantage of these features, Constantino et al. (2007a) compared teacher- and parent-report SRS scores in a large sample ($N = 577$) of clinically referred children. A PDD-affected sample ($n = 271$) was compared to nonaffected siblings ($N = 119$). Parent and teacher forms were both administered and the screening power reported when both reports on a given child were elevated to the diagnostic cut point. Under these conditions the ROC analyses showed an $AUC = .95$ with sensitivity 0.75 and specificity 0.96.

Results in Other Clinical and Behavioral Research

While the SRS has the identification and characterization of ASDs as its central purpose, it has been used in studies of other behavior difficulties and clinical diagnoses. In all of the studies reported below, children with non-ASD clinical diagnoses are seen to have clinically relevant weakness in the kinds of social behavior assessed by the SRS. As noted by one of the teams (Pine et al. 2008), this can raise the question of whether ASDs are being under-assessed when there are comorbid conditions. More broadly, however, all of the findings show that the behavioral and social problems associated with ASD can have relevance in other areas. The SRS measures these problems in a way that is sensitive to their

presence, differentiated in elevation from that seen in actual ASD diagnoses, and may be highly sensitive to treatment effects (Puleo and Kendall 2011).

Heritability/Genetic Epidemiology

In an extensive line of research employing the SRS in large genetically informative samples of twins (Constantino and Todd 2000, 2005; Ho et al. 2005), siblings (Constantino et al. 2006; Schwichtenberg et al. 2010), and families (Virkud et al. 2009), representing both the general population Constantino and Todd (2003) and clinically affected families (Constantino et al. 2010), including studies involving molecular genetic markers (Duvall et al. 2007; Campbell et al. 2010; Coon et al. 2010), it has been shown that the quantitative traits measured by the SRS are highly heritable across the entire range of severity in which they occur in nature (from mild to severe), and that subclinical autistic traits characterized by mild elevations SRS scores constitute candidate endophenotypes, that is, genetically related to the cause(s) of autism itself.

Brain Imaging

Several neuroimaging studies have elucidated brain imaging phenotypes that relate closely to variation in SRS scores, both in the general population and in clinically affected samples (Assaf et al. 2010; Di Martino et al. 2009; Kaiser et al. 2010; Paul et al. 2010).

Longitudinal Course

Constantino et al. (2009) tested $N = 285$ (95 male twin pairs ASD affected and 95 male typical developing) longitudinally over a 5-year period, and found that test retest correlations maintained around $r = .90$ in both groups. Individual trajectories varied as a function of severity at baseline. Moderate improvement with age was noted, underscoring the instrument's potential utility for ascertaining incremental response to intervention. Ongoing research on the longer-term longitudinal course of autistic traits and symptoms among clinically affected children and their siblings is underway in NIH-funded research.

Social Security Amendments of 1965 (or “Medicare Act of 1965” and/or the “Medicaid Act of 1965”)

Annemarie M. Kelly and Christina N. Marsack-Topolewski

College of Health and Human Services, Eastern Michigan University, Ypsilanti, MI, USA

Definition

The Social Security Amendments of 1965 (the “Amendments”) are the milestone laws that established the U.S. Medicare and Medicaid programs (Pub. L. No. 89–97). Collectively, these federal statutes have four major provisions: (1) a hospital insurance program for qualifying adults aged 65 and older (Medicare Part A, Title XVIII); (2) a medical insurance program to offset out-of-pocket healthcare costs for qualifying adults aged 65 and older (Medicare Part B, Title XVIII); (3) increased government benefits through the Social Security program (formerly called the “Old-Age, Survivors, and Disability Insurance” system in Medicare Part B, Title XVIII); and (4) improved the federal-state public assistance programs for qualifying adults with low incomes (Medicaid, Title XIX).

Congress’ expansion of the Social Security Act with the Amendments of 1965 marked a pivotal moment in U.S. healthcare policy. Federal Medicare and state Medicaid systems have evolved over time based on the legal foundations set forth in 1965 (Martin and Weaver 2005). Millions of Americans have received government benefits from one or both of the programs since their inception.

Individuals with autism spectrum disorder (ASD) and their caregivers should be knowledgeable about the government-sponsored benefits that are available under the Amendments of 1965 and their legal precedent (Bowen 2014).

Medicare Legislative Details

The Amendments of 1965 added Title XVIII (18) to the Social Security Act to create the first regulations for the Medicare program (Cohen and Ball 1965). Medicare helps qualified individuals to access healthcare services. In its first iteration, Medicare was a welfare program that only served adults age 65 and older who received government financial aid. Over time, federal lawmakers have expanded the Amendments of 1965 so that Medicare also covers individuals with disabilities of all ages (as defined by Social Security Administration (SSA) rules) as well as individuals with end-stage renal disease (DeWitt 2010).

Medicare is administered by the Centers for Medicare & Medicaid Services (CMS), which is a government agency within the U.S. Department of Health & Human Services (DHHS). Since 1965, Congress has worked with CMS to provide additional benefits (DHHS CMS 2020a). The first version of Medicare included part A for hospital insurance and part B for medical insurance. These two parts are often referred to as “Original Medicare.” Today, Medicare services are divided into four primary areas: part A for inpatient/hospital coverage, part B for outpatient/medical coverage, part C for supplemental healthcare benefits, and part D for prescription drug coverage.

Per the Amendments of 1965, Medicare coverage is limited to items and services that are medically “reasonable and necessary” for the diagnosis or treatment of an individual’s illness or injury. Because healthcare technology, medical services, and healthcare economics are continuously evolving, CMS updates its guidelines regularly to help providers and Medicare beneficiaries navigate program requirements.

Medicaid Legislative Details

Title XIX (19) in the Amendments of 1965 established the first regulations for the Medicaid program. Medicaid provides state governments with the opportunity to receive federal funds for a portion of the services that it provides to people with limited incomes (DHHS CMS 2020b).

Whereas Medicare is a federal program, Medicaid programs are largely administered by their respective state governments. Under the Amendments of 1965, each Medicaid program is jointly funded by both federal and state budgets. The amount of money that each state receives from the federal government for its Medicaid program varies under Federal Medical Assistance Percentage (FMAP) rules (Mitchell 2018).

Each state’s Medicaid system must comply with federal statutes and administrative regulations from CMS. These federal rules set the minimum criteria for enrollee qualifications, billing procedures, and benefit categories. The nature and extent of Medicaid services varies widely between state programs. As long as they comply with federal legal standards as a baseline, state Medicaid agencies can design and implement additional procedures and policies to best serve their residents.

Legislative Details for Other Key Provisions

Titles XIX and XVII created several policies that protect the sensitive health information of program enrollees. These laws were among the first of their kind to govern collecting, using, and disclosing personal health information. The US lawmakers have used the guidelines from the Amendments of 1965 to create other milestone laws that safeguard medical records, such as the Health Insurance Portability and Accountability Act of 1996 (“HIPAA,” Pub. L. No. 104–191).

The 1965 Amendments also enacted new legal requirements for Social Security Disability Insurance (SSDI). Whenever a person is able to collect workers’ compensation payments, SSDI benefits must be reduced in accordance with SSA guidelines (Reno et al. 2005). Under the 1965 Amendments, a person’s total earnings from SSDI and workers compensation cannot result in a reduced income – the total amount of reduced SSDI and workers’ compensation payments can never be less than what the individual received in SSDI before he or she became eligible for workers compensation. These policies are often referred to as

the “workers’ compensation offset” for SSDI payments.

Legislative History and Background

The 1965 Amendments’ provisions were heavily debated in the 89th Congress (U.S. Social Security Administration [n.d.](#)). The House of Representatives approved the Amendments on April 8, 1965. On July 9, 1965, it was approved in the Senate. President Lyndon B. Johnson signed the Amendments into law on July 30, 1965.

The momentous Medicare and Medicaid statutes were the result of years of national deliberation about the need for government-sponsored healthcare coverage programs. In passing these Amendments in 1965, federal lawmakers recognized that a significant population of Americans could not access medical goods and services because they could not obtain health insurance from private providers. Specifically, expert reports to 89th Congress concluded that two key issues prevented many individuals from accessing private health insurance: either they could not afford to make out-of-pocket payments to a private insurer or they were unable to work and obtain employer-sponsored health coverage (Berkowitz [2005](#)).

Findings from the 1950 American Census were one of the driving forces behind the Amendments of 1965. Statistics in the 1950 Census established that the United States had a steadily aging population with individuals living longer lifespans than ever before (U.S. Department of Commerce Bureau of the Census [1975](#)). At the same time, the census also found that the majority of adults age 65 and older, as well as individuals with disabilities, were either uninsured or had only minimal health insurance coverage (often referred to as “underinsured”) (U.S. National Archives and Records Administration [2020](#)).

Since 1965, a large body of health law and policy scholars have praised Medicare and Medicaid while recommending program expansions (Moore and Smith [2005](#)). At the same time, a

different cohort of scholars contend that the systems’ financing structures are overly broad, among other concerns. Though Medicare and Medicaid policies have advanced since their establishment in 1965, many of the fundamental program goals and baseline benefits remain the same today. Lawmakers have expanded on the foundational ideas in the 1965 Amendments to provide more Americans with access to healthcare through Medicaid and Medicare. Over time, Congress has also increased the types of services available through the programs. In 1973, Congress made a ground-breaking modification to the Amendments of 1965 that allows people of all ages with long-term disabilities to access Medicare.

Over the years, judicial court opinions from the U.S. Supreme Court and case decisions from other lower courts have established guidance for interpreting the 1965 Amendments’ various provisions (often called “legal precedent”). Federal and state administrative rules – typically from CMS and state health departments – also provide legal insight about Medicare and Medicaid program requirements in specific circumstances. This information is available online in the form of agency regulations, registers, manuals, and memoranda (e.g., DHHS CMS [2020c](#)) and State of Michigan DHHS [2020](#)).

Though Congress and government agencies have made numerous modern developments to Medicare and Medicaid laws, many of the central provisions from the 1965 Amendments are still in use today – these include the goal to reduce barriers to medical care for America’s most economically vulnerable citizens.

Social Skill Interventions

M. S. Hope Morris

Communication Sciences and Disorders, The University of Vermont, Burlington, VT, USA

Definition

Social skill interventions attempt to remediate deficits in the set of social skills that are used to interact and communicate with others. For individuals with autism spectrum disorders (ASD), this means difficulties in initiating interactions, sharing enjoyment, sustaining reciprocity, taking the perspective of another, and making inferences about the interests of others. Social skill deficits are a central feature of ASD. There are many different programs established to treat these social skill deficits for individuals with ASD; however, many programs are not well researched and do not have an established evidence base.

Historical Background

The social skill deficits noted in autism spectrum disorder (ASD) were first described in papers published in 1943, one in English and one in German. Leo Kanner (1943) described 11 children

with “early infantile autism” in his paper “Autistic disturbances of affective contact” and highlighted poor social relatedness as a key component of the disorder. Hans Asperger (1944) in Vienna, Austria, submitted a thesis on “Autistic psychopathy in childhood” and described four children with “autistic psychopathy.” He identified these children with “deficient social behavior.” Since this time, significant developments have been made to help us understand the neuropsychological underpinnings of social cognition. The notable work of researchers in the area of social cognition and theory of mind, including Dr. Baron-Cohen in England and Dr. Tony Attwood in Australia, has helped the profession and community gain a better understanding of the core social cognitive processes involved in the social interaction deficits characteristic of individuals with ASD. In addition, Dr. Temple Grandin, an individual with autism, has provided invaluable insight into the neurological strengths and challenges in autism, with her book “Thinking in Pictures” (1995), including difficulties understanding the social rules of interaction and developing relationships with other people. In recent years, there has been an increase in the awareness of the benefits of early intervention in ASD and the need for opportunities for social engagement. With this awareness has come a growing interest in developing early social communication skills including joint attention and symbolic play. Current researchers in this area include Dr. Peter Hobson, Dr. Connie Kasari, Dr. Peter Mundy, Dr. Barry Prizant, Dr. Sally Rogers, Dr. Laura Schreibman, and Dr. Amy Wetherby, among others. Practitioners, like Michelle Garcia Winner (2006), have described specific social cognition intervention strategies and developed social skills programming to assist professionals in intervention.

Rationale or Underlying Theory

Deficits in social interaction are one of the three core characteristics of autism spectrum disorder (ASD). Difficulties in engagement and socialization have far-reaching implications throughout childhood and into adulthood. Deficits in social

cognition impact the development of relationships with others, academic and vocational success, as well as mental health and quality of life. Based on current research, early intervention that focuses on building joint attention, a pivotal skill leading to later development of language and social communication, is key to fostering and developing social engagement with others. Social skills intervention is an important part of any intervention program for children and adolescents/adults with ASD.

Goals and Objectives

Social skills intervention is intended to teach both pragmatics (the social use of language) and social cognition (theory of mind, perspective taking), the latter being a critical component for children with ASD. Teaching pragmatic language skills can entail the (1) use of language (greeting, informing, demanding, promising, requesting), (2) changing language according to the needs of the listener or situation, and (3) following rules for conversation and storytelling (taking turns, introducing topics, staying on topic, rephrasing, using verbal/nonverbal signals, facial expressions/eye contact, proximity). Social cognitive aspects are addressed by teaching individuals to take the perspective and to perceive the thoughts and intentions of others. These skills are often best taught by making the abstract as “concrete” as possible, using visuals and pictures to represent abstract concepts.

Treatment Participants

Participants in social skills intervention can vary in age, skill development, and diagnosis. Children with social skill challenges span the range of developmental disabilities from those with specific learning disability and specific language impairment to those with ASD. For young children with ASD, the focus of intervention is establishing joint attention and sharing positive affect/engagement with others during play and people games/routines. During elementary and middle school, social skills intervention may be

more focused on teaching specific pragmatic language skills as well as how to engage in group activities. For children that have Asperger syndrome or high-functioning autism, a focus on teaching social cognition skills begins early as these social cognitive differences are a hallmark of these disorders.

Treatment Procedures

Social skills intervention for young children with autism spectrum disorder (ASD) often occurs during parent-child interactions. Teaching parents to engage their young children with ASD has positive outcomes on skill development and can allow for parents to help their children engage with neurotypical peers. Small group settings are often utilized to teach children with autism how to play cooperatively with others. These groups are often facilitated by an educator or speech-language pathologist. For school-age children, social skills intervention occurs in groups of similarly aged peers and can include neurotypical peers as models of prosocial behavior. These groups are often facilitated by an educator, speech-language pathologist, and/or a psychologist and can occur within the school setting or privately. Social skills intervention for the older child or adolescent with ASD entails a focus on social cognition. Often a cognitive behavioral therapy (CBT) approach is utilized to address deficits in theory of mind and perspective taking. Typically, those social skills taught include turn-taking, sharing, initiating, playing with friends, having a conversation, suggesting play ideas, giving compliments, understanding jokes and idiomatic expressions, showing affection, and perspective taking. There are also a range of intervention strategies that support social skill development including peer mediation, social stories and comic strip conversations, video modeling, integrated playgroups, ILAUGH model, etc. Evidence-based programs utilize similar strategies for teaching social skills. Skillstreaming (McGinnis and Goldstein 1997) utilizes modeling, role-playing, specific feedback, and skill transfer with homework activities to develop

competence in interpersonal conflict resolution and to learn self-control of behavior. The Second Step program (Borch 2002) contains in-school curricula, parent training, and skill development to teach socioemotional skills. Teaching strategies include modeling, coaching, group decision making, and direct skill practice. Cognitive behavioral techniques (CBTs) have been applied to the remediation of social deficits and involve the use of “self-talk” strategies to modify overt behaviors (Mahoney 1974; Meichenbaum 1977). Utilizing these techniques in social skills intervention, according to Kendall (1993), involves cognitive, behavioral, developmental, and emotive strategies that include modeling, role-playing, reinforcement, and self-evaluation. CBTs have been utilized by specific practitioners to develop social skills intervention for individuals with autism spectrum disorder (ASD), including the social thinking curriculum (Winner 2006).

Efficacy Information

Based on a review of four recent, critical reviews of social skills intervention research (Bellini et al. 2007; Matson et al. 2007; Rao et al. 2008; White et al. 2006), there is currently limited evidence for the effectiveness of group social skills intervention. Current research lacks control groups for comparison and lacks blind observers to evaluate results. All studies lack generalization techniques to demonstrate use of skills across settings. Further, there is limited longitudinal research to determine maintenance of skill acquisition, and, in many cases, there is a lack of consensus on a common definition of what comprises social skills. Of particular note is the study by Bellini et al. (2007) reviewing school-based social skills group intervention. Overall, there is a lack of evidence that children with ASD are receiving effective social skills intervention in the school setting. Recommendations based on these reviews include the need for a manualized social skills curriculum, the use of rigorous research designs to assess the effectiveness of intervention, the consistency in measurement, and the implementation of generalization measures.

Outcome Measurement

There are few assessment instruments that are able to adequately measure social skills across a variety of contexts. Standardized tests are typically not adequate in sensitivity measures to assess these skills. However, standardized measures exist that consist of parent, teacher, and individual rating scales and provide a view of social skills development that considers the impact on communication, academic performance, and behavior. Measures such as the *Social Skills Rating System* (SSRS; Gresham and Elliott 1990) and the *Vineland Adaptive Behavior Scales*, Second Edition (Vineland II; Sparrow et al. 2005) are often utilized as standardized measures of social skill development. Other standardized measures specific to measuring skills in autism spectrum disorder (ASD) include the *Autism Social Skills Profile* (ASSP; Bellini 2006), the *Social Responsiveness Scale* (SRS; Constantino and Gruber 2005), and the *Social Communication Questionnaire* (SCQ; Rutter et al. 2003). These standardized measures should be paired with observations of social interactions in natural settings (home, school, group activities). A focus in the literature at this time is the limited generalization of social skills across environments and contexts. More rigorous research designs and targeted evaluation of social skills are needed to determine the efficacy of social skills intervention.

Qualifications of Treatment Providers

Individuals providing social skills intervention should have training and experience in working with individuals with autism spectrum disorders. These licensed professionals may include psychologists, speech-language pathologists, social workers, and educators. Individuals with some form of psychological training can be well versed in teaching skills to adolescents and can address some of the concomitant behavioral and psychological issues that can be present (depression, anxiety, etc.).

Description

The Social Skills Improvement System (SSiS; Gresham and Elliott 2008) Rating Scales assist professionals in screening and classifying students ages 3–18 years suspected of having significant social skills deficits. The SSiS Classwide Intervention Program and SSiS Intervention Guide are manualized treatment programs for eliminating or reducing social skill deficits identified on the SSiS Rating Scales. The SSiS uses a multirater (parents, teachers, and students with at least third-grade reading ability) approach that provides a comprehensive examination of seven areas of prosocial skills (communication, cooperation, assertion, responsibility, empathy, engagement, and self-control) and five areas of problem behaviors (internalizing, externalizing, bullying, hyperactivity/inattention, and autism spectrum). The instrument yields norm-referenced scores based on a national sample representative of the 2006 US Census.

Given that autism is characterized by impaired social interactions, problems with verbal and nonverbal communication, and repetitive/stereotyped behaviors, the SSiS Rating Scales and related intervention manuals offer professionals a focused screener for autism spectrum disorders within a comprehensive content of social behavior. The SSiS Autism Spectrum Subscale is comprised of 15 items, 8 from the Social Skills Scale (e.g., interacts well with other children, makes eye contact when talking, uses gestures or body appropriately with others) and 7 items from the Problem Behavior Scale (e.g., is preoccupied with object parts, becomes upset when routines change, repeats the same thing over and over). The items on both the Social Skills Scale and Problem Behavior Scale are rated on a 4-point scale (0 = Never, 1 = Seldom, 2 = Often, 3 = Almost Always). Low-frequency ratings on the eight social skills items, whereas high-frequency ratings on the problem behavior items are indicative of a possible autism spectrum disorder and thus should be followed up with a more comprehensive assessment.

Historical Background

The SSiS Rating Scales originally was published in 1990 as the *Social Skills Rating System* (SSRS; Gresham and Elliott 1990). The SSRS was reportedly used by many professionals as part of their autism screening efforts; however, the SSRS was not designed with autism or autism spectrum disorders in mind. When the revision of the SSiS was being conceptualized, the authors consult with educators serving autistic children and the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed., 1994) of the American Psychiatric Association and the National Research Council's report (2001) on *Educating Children with Autism* to ensure they were sensitive to critical identifying behaviors and conditions.

Psychometric Data

The SSiS-RS manual provides extensive validity evidence based on test content, internal structure, intercorrelations among scales and subscales, item-total correlations, and relations with other variables (Gresham and Elliott 2008). Item development of the SSiS-RS was based on a broad review of the empirical literature on social skills deficits in special populations, reviews of published empirical studies using an earlier version of the scale (Social Skills Rating System, Gresham and Elliott 1990), and research on the relationship between specific social behaviors and important social outcomes for children and youth. Intercorrelations among scales and subscales for each form are moderate to high for the social skills and problem behavior scales. Item-total correlations across forms by age tend to be moderate to high, many of which exceed 0.70–0.80.

Correlations between the SSiS-RS and the Behavior Assessment System for Children, Second Edition (BASC-2; Reynolds and Kamphaus 2004), are moderate to high, depending on the scales and subscales. For example, the median correlations between the SSiS-RS total social skills score and the teacher form of the BASC-2 social skills score are 0.78 and 0.69 for the teacher and parent forms, respectively. Correlations

between the SSiS-RS total social skills scores and the socialization scores of the Vineland Adaptive Behavior Scales, Second Edition (Vineland II; Sparrow et al. 2005), are 0.65 and 0.44 for the teacher and parent forms, respectively.

Using a sample of 50 students with an autism spectrum disorder as diagnosed by the DSM-IV-TR, a known group comparison analysis with a nonclinical sample was conducted. On the teacher and parent forms of the SSiS, all the mean score differences were statistically significant. The Social Skills Scale means of 74.6 and 75.8 were at least 1.5 standard deviations lower than the nonclinical reference sample of students. Conversely, the scale means for the problem behaviors on both forms were more than 1 standard deviation higher than for the nonclinical reference group. The greatest differences were on the Autism Spectrum Subscale, where the scores of 23.9 and 22.6 were nearly 2 standard deviations higher than the nonclinical reference group mean. These results are consistent with expectations that individuals with autism spectrum disorder have major deficiencies in social skills and tend to exhibit more problem behaviors, thus lending substantial support for the validity of the scores of this subscale as a measure of behaviors typically exhibited by individuals diagnosed with autism.

Clinical Uses

The SSiS Rating Scales – teacher, parent, and student forms – are intended to be used as a comprehensive measure of children's social skills and a useful screener of children's problem behaviors. In particular, these rating scales are designed to identify social skills acquisition and performance deficits in areas of communication, cooperation, assertion, responsibility, empathy, engagement, and self-control.

The Autism Spectrum Subscale is designed to facilitate a time-efficient and contextualized screening measure. By using the nationally representative norming sample for comparison, it is possible to get a clear comparison between a student suspected of an autism spectrum disorder to a

same age and sex comparison group of nonclinical students.

Scores on the SSIS Rating Scale items can be analyzed using the Social Skills Analysis of Behavior to identify strengths, performance deficits, and acquisition deficits. Based on the analysis, items can be aligned or linked to a skill unit in the SSIS Classwide Intervention Program (CIP) to be taught using a manualized lesson plan. The SSIS CIP is a highly effective intervention program as document in several recent randomized control trial (RCT) investigations with first, second, and third grade students.

Social Stories

Susan A. Mason

Services for Students with Autism Spectrum Disorders, Montgomery County Public Schools, Silver Spring, MD, USA

Definition

A social story is a brief story that describes a social situation including cues and appropriate responses.

Historical Background

Social Stories™ were first developed, introduced, and trademarked in 1991 by Carol Gray. They are generally regarded as a positive intervention strategy with some components of priming. Social Stories™ were developed so that students with autism spectrum disorders (ASD) could learn social skills. They are written and tailored to the individual with ASD to help him or her understand and respond appropriately in various social situations.

Originally, social stories were written using three types of sentences: descriptive, directive, and perspective taking. Descriptive sentences provided an overview of a social situation in terms of relevant social cues. Directive sentences specified an appropriate response, and perspective sentences described the feelings and responses of both the individual with ASD and others represented in the target social situation. Ms. Gray specified a specific ratio of sentences to be contained within each Social Story™. Also, initially, Social Stories™ were presented as text,

and the individual with ASD was encouraged to read them by himself or herself.

Over the years, in recognition that not all students with ASD were able to read and comprehend Social Stories™, the process for writing these stories has changed dramatically. Ms. Gray originally discouraged the inclusion of illustrations as she felt that a student may be distracted by them or misinterpret the situation based on an illustration. Today, it is commonplace to supplement social story text with pictures in the forms of photographs or Mayer-Johnson™ Picture Communication Symbols or to use PowerPoint and computer-assisted presentation of Social Stories™. Social Stories™ also have been presented in the form of Comic Strip Conversations™, news articles, and research articles. Ms. Gray emphasizes presenting Social Stories™ in a format that is motivating to the individual with ASD. Other changes to the development and presentation of social stories are the revision of the types of sentences used within a social story; social stories now include the following: descriptive, directive, perspective, affirmative, control, cooperative, and partial sentences. As described by Ms. Gray, affirmative sentences may express a commonly shared value or feeling, and they serve to enhance the meaning of statements. Control sentences are written by the individual after he or she reviews the social story and are used to identify personal strategies that will help him or her recall and implement skills that are outlined in the social story. Cooperative sentences are sentences that point out ways that others will assist the individual. Finally, partial sentences promote prediction and encourage the person with ASD to guess the next step in the situation. It should be noted that, at this time, control and cooperative sentences are optional when writing Social Stories™. There is a recommended ratio of zero to one directive or control sentences and between two and five descriptive and/or perspective sentences in a Social Story™. Despite these expansions of the form of a social story, the intent remained to use it as an antecedent condition to teach students with ASD to recognize and respond to a wide array of social contexts.

Rationale or Underlying Theory

Some have described the rationale for using Social Stories™ as one that teaches persons with autism spectrum disorder to develop theory of mind (perspective-taking skills). Carol Gray does not present a theory but rather describes the goal of Social Stories™ is to share accurate social information in a patient and reassuring a manner that is easily understood by its audience. Half of all Social Stories™ developed should affirm something that an individual does well. Although the goal of a Story™ should never be to change the individual's behavior, that individual's improved understanding of events and expectations may lead to more effective responses.

An alternative explanation for the use of social stories is that it involves a shared schema or background knowledge and allows one to “build a scaffold of understanding for a schema (mental representation) that an individual does not yet possess” (Reynhout and Carter 2006). Myles and Simpson (2001) suggested that Social Stories™ provide access to the “hidden curriculum” (the dos and don'ts understood and adhered to by everyone except those with ASD) inherent in social situations (Reynhout and Carter 2006).

Goals and Objectives

As previously mentioned, the goal of a social story is to share important information about a social context. Information is shared in a way that is age appropriate to the student with ASD and ideally allows him or her to read about and be more “comfortable” in social situations. Social Stories™ have been used to teach a variety of skills including following routines, academic skills such as math, social situations such as playing at recess, having a conversation, and respecting personal space. As noted by Gray and Garand (1993), “Generic Social Stories™ can be used to describe social situations frequently experienced by children with autism which can be individualized and adapted as the need arises.”

Treatment Participants

Traditionally, persons with ASD have participated in the use of Social Stories™. Initially, Social Stories™ were recommended for use with students who have ASD and who have the ability to read and who are considered individuals with “high-functioning” autism.

Treatment Procedures

Social Stories™ are written according to the guidelines published by Carol Gray. Several considerations are necessary when writing Social Stories™. These considerations include the need to maintain the perspective of the student for whom the story is written, keep the story within the student’s comprehension level, and include appropriate vocabulary and size of font for their reading ability. Behavioral responses should be stated in positive terms, that is, label what you want the student to do, rather than what they should not do, and Gray and Garand (1993) recommend that students demonstrate intellectual ability in the range of 35–55 on a standardized IQ test (Reynhout and Carter 2006). Additionally, it is important to determine whether text will be supplemented with pictures and if pictures will be photographs, Picture Communication Symbols™ (Mayer Johnson), or embedded in a PowerPoint presentation.

Once social stories are developed, they are to be read to the child who is unable to read them independently. Reading of the Social Story™ should happen in advance of entering into the social situation, and there should be a time to check for comprehension. In summary, social stories are written according to the guidelines set forth by Carol Gray, and then read to or with the individual with ASD, after which, a comprehension check is made. Comprehension can be checked either orally or in writing by having the student answer a series of questions about the social story. There currently are no hard-and-fast guidelines about the frequency of using Social Stories™; however, it is noted that they can be faded over time.

Efficacy Information

To date, there is limited data on the efficacy of social stories. Studies that have been conducted have yielded mixed results. For example, Social Stories™ have rarely been evaluated exclusively; usually, they incorporate some other form of treatment such as role play, modeling, rehearsal, written checklists, and token rewards. The implementation of Social Stories™ also has varied from study to study. For example, those that have used social stories have varied the frequency of presentation as well as the setting for presentation (home, in class, outside of a classroom). They also have used Social Stories™ to follow up with a situation if there is a misperception by the student. In this situation, social stories are used as an antecedent and consequence, and, during the consequence portion, the reader highlights the information that was misinterpreted.

Variations in presentation, use, and style of Social Stories™ make it difficult to interpret the data. Of studies that have been conducted using single-subject research methodology, results have been mixed. Some researchers have noted initial gains using Social Stories™, yet the gains are short lived, and there is lack of maintenance and generalization. Efficacy of Social Stories™ may also have been compromised. There is literature to suggest that there has been inconsistency in conforming to the guidelines for writing social stories. At best, current research data for Social Stories™ does not support them as an evidence-based practice; however, they continue to be used due to clinical popularity and the belief that they represent best practice strategies for students with ASD (Smith 2001 in Reynhout and Carter 2006).

Outcome Measurement

Currently, outcome measurement for Social Stories™ is limited. There are a few studies that have been conducted, and many of these studies have some methodological flaw(s). There are limited studies and/or review of the literature that address the efficacy of social stories; of those available, analysis of the results remains varied

and inconclusive, suggesting that more research is needed.

Qualifications of Treatment Providers

There are no hard-and-fast qualifications for treatment providers; rather, one simply needs to be able to follow the guidelines set forth by Carol Gray. Treatment providers can be teachers, speech-language pathologists, parents, counselors, and other significant adults who work with or are familiar with the person with ASD.

²Koegel Autism Center/Department of Counseling, Clinical, and School Psychology, University of California Santa Barbara, Santa Barbara, CA, USA

Definition

The Social Tools And Rules for Teens (START) socialization program for adolescents with autism spectrum disorder (ASD) is a peer-facilitated intervention that combines experiential learning opportunities with an interactive social curriculum. It is a 20-session program consisting of weekly 90-min group meetings. Each meeting consists of an individual check-in session, a free socialization period, a social topic discussion, a structured social activity, and a checkout

session. Structured and unstructured free socialization periods are embedded within each group session to provide a supportive, natural context for social experimentation, self-management, and skill building. The interactive didactic social lessons are intended to provide opportunities to promote social insight and effective social skill use. The START program was developed at the University of California, Santa Barbara.

Historical Background

By the nature of their diagnosis, adolescents with ASD often experience limited social success due to challenges with social skills, insight, and motivation (Orsmond et al. 2004). These limited social competencies can leave these individuals vulnerable to social rejection or exclusion (Schroeder et al. 2014), limiting their access to the peer interaction needed to actually improve their social skillset. Many adolescents with ASD experience lower perceived social status, friendship quality, and social motivation, along with greater levels of loneliness than typically developing peers (Locke et al. 2010; Mazurek 2013). Fortunately, there has been a recent increase in empirically supported social skill interventions that attempt to address these challenges and generate crucial social momentum (Miller et al. 2014).

A supportive network of peers is a crucial, yet often overlooked, component in socialization efforts. Fortunately, the use of peer-mediated interventions is growing in popularity (Watkins et al. 2015). Typically-developing peer models are valued for their ability to connect with same-aged participants and model, teach, and constructively evaluate social performance. They are also immersed in the same unique peer social culture as the target population and can provide much more ecologically appropriate instruction than a generic social skills curriculum taught by adult clinicians. Through these positive interactions, individuals with ASD also gain exposure to unconditional social acceptance – exchanges with receptive peers who are friendly, willing to converse, and forgiving of social missteps. Having positive experiences with peers allows

adolescents with ASD to build social momentum that increases both confidence and competence to interact.

The initial pilot of the START program was developed to improve social competence in adolescents with ASD through the use of immersive experiential learning techniques (Vernon et al. 2016). This process of learning operates through exposure to and processing of real-world experience (Kolb 2014). A socialization intervention that incorporates experiential learning allows participants to engage with peers and experiment with social strategies firsthand, reflect on these experiences, and learn from their mistakes. Instructional social skills lessons also have value; however, many of the social nuances associated with live interactions are unable to be replicated when teaching a didactic lesson. Individuals often learn best by doing. This process is analogous to learning a sport or musical instrument. Some gains can be made through professional instruction, tutoring, and practice exercises, but one can only master a skillset through repeated live, real-world performances. By actively engaging in a naturalistic social setting with typically developing peers, individuals can benefit from the social complexities inherent in real-world interaction. Moreover, these active learning opportunities allow individuals to experience the natural incentives of positive peer interactions, such as discussion of favorite topics, responses to humor, and opportunities to jointly engage in enjoyable activities. By practicing social interactions in a safe, welcoming environment, participants can begin to associate social engagement with rewarding positive experiences and outcomes. The efficacy of the START program has been further established through the outcomes of a randomized clinical trial (Ko et al. 2018; Vernon et al. 2018).

Rationale or Underlying Theory

In order to better understand the design and conceptualized mechanism of change of the START program, it may be helpful to explore its theoretical underpinnings. The model is grounded

in an experiential model of social learning. Experiential learning theory is conceptualized as a four-stage learning process (Kolb et al. 2001) in which (1) an experience serves as the stimulus for (2) reflective observation on what is functionally working or failing to work in the learning context, which (3) solidifies one's abstract conceptualization of a given phenomenon. Based on this accrual of knowledge, the individual is able to engage in (4) active experimentation to hone one's knowledge base and associated skill set, which is then applied to future experiences as the cycle repeats.

When applied to socialization and conversational competence, experiential learning is heavily reliant on sustained immersion in an appropriate social environment (Baker et al. 2002). Mapped onto the four-stage experiential learning process, interactions with others provide an experiential stimulus that allow individuals to reflect on their interpersonal successes and failures, improve their understanding of successful social strategies, and modify subsequent social bids to improve the likelihood of success in future engagements. For the general adolescent population, the accumulation of these interactions appears to be crucial for establishment of social competence and seems to be predicated upon two interrelated factors: (a) the willingness (or motivation) of the individual to engage with available social partners and (b) the willingness of these partners to be responsive to the social bids of that individual.

Goals and Objectives

The START program is designed to improve the social readiness skills of adolescents with ASD. Social readiness can be conceptualized as the combination of two essential components needed for optimal interpersonal functioning: social motivation and social competency. In turn, social competency can be further broken down into mastery of social insight and social skills (Vernon et al. 2016). The START socialization curriculum was intentionally designed to integrate both experiential and didactic training components

within a single peer-facilitated intervention to target these components.

Social Motivation

Social motivation is the desire to voluntarily engage in social pursuits and the anticipation that one will derive pleasure from such interactions, serving as a popular conceptualization of autism-related vulnerabilities (Chevallier et al. 2012; Dawson et al. 2005). Social motivation is a prerequisite that makes social immersion and experiential learning possible. At its foundation, the START program was intended to maximize the motivation of individuals who are interpersonally vulnerable. A safe, accepting space was fostered for practicing social skills without the fear of rejection or judgment. Group cohesion and unconditional acceptance were emphasized. By creating a supportive experiential context, the participants were granted the opportunity to become fully immersed and accepted by a peer group, which then became the ideal forum to practice and master critical social competencies. Over the course of 20 weeks, they accumulated frequent, reoccurring experiences of social success to establish both confidence and valuable social momentum.

Social Insight

Social insight is the understanding of underlying principles that govern successful social behavior, encompassing various concepts of social cognition (i.e., empathy, theory of mind, problem-solving capacities, and executive functioning skills; Schmidt et al. 2011). Several program components were specifically incorporated into the program to foster social insight. The check-in and checkout phases of each group provided a private forum to intentionally reflect on one's social experiences and process perceived success and failure. Participants were also encouraged to think through role-plays and videos and describe the reasoning behind certain social decisions. Finally, during group topic discussions, the rationale underlying the use of certain social strategies was explored and explicit links were made to principles of empathy, courtesy, respect, and constructive problem solving.

Social Skills

Finally, social skills describe specific behaviors that are employed in the proper context at the proper time to facilitate a successful person-to-person exchange. The hands-on activities and self-management components of the START program facilitated the development and mastery of this concrete social skillset. Individual skills were modeled, practiced, and critiqued each session. Intentional practice redundancies were also used to promote eventual automaticity of skill use. Specifically, individualized target skills were practiced during check-in, self-managed during group, and assigned as homework in between group sessions. Similarly, weekly skills highlighted in the group curriculum were critically analyzed during role-play sessions and video examples, demonstrated, practiced in pairs, and assigned as weekly social homework.

Treatment Participants

The inclusion criteria for START program participation includes an age between 12 and 17 years, a diagnosis of autism spectrum disorder, a verbal IQ score above 70, and the ability to comprehend and speak in full sentences. To date, only an English language version of the START program has been evaluated. Because the program relies on the use of conversation, discussion of social issues, and self-reflection, it is likely not suitable for individuals with more limited language skills or intellectual impairment (although an adapted version of the START program for individuals with higher support needs is currently in development).

Treatment Procedures

The START program consists of 20 weekly sessions that are 90 min in length. Each meeting consists of a 5-min individual check-in session, a 20-min free socialization period, a 40-min social topic discussion, a 20-min structured social activity, and a 5-min checkout session that parents are invited to join.

Pre-group Preparation

Prior to beginning the program, participants complete an initial 90-min intake session, which consists of obtaining consent/assent from parents and adolescents, obtaining basic demographic information, and completing all required intake measures. Trained undergraduate-level research assistants conducted all intakes and subsequent progress meetings. During the pre-intervention session, an assessment of individual social vulnerabilities was conducted. Participants and parents were provided with a list of common social skill difficulties/vulnerabilities and also had the option to write in additional concerns that were not listed (Vernon et al. 2016). Based on a rank order of specific social skill difficulties completed separately by each adolescent, their parent, and an intake clinician, consensus was reached on an individual social skill to serve as the initial focus of self-management. The primary objective was to directly target the social skill deficit that was identified as having the largest negative impact on each adolescent's level of social success.

The primary facilitator discussed the target skill with the adolescent and they jointly practiced self-management procedures (monitoring and tracking one's use of a particular social skill). Specifically, the skill was operationally defined for the participant, modeled by the social facilitator, and then practiced in a brief conversational exchange while the participant tracked their skill use using a small digital tally counter. After the participant could verbally describe the target social skill and successfully demonstrate accurate self-management in conversation, they were encouraged to continue self-managing use of this skill during each START group session. Individual goals were reexamined every 5 weeks and a new primary skill was introduced as participants either (a) demonstrated adequate mastery of a previous target skill or (b) exhibited a more significant challenge in another skill domain that was identified as a more notable source of social difficulty.

START Program Session Format

START program sessions: All of the adolescents began participation in the START program within

2 weeks of completing all pre-intervention measures. The 90-min weekly program consisted of the following phases: an individual therapeutic check-in session, a group unstructured socialization time, a structured group activity, a group discussion and practice of a social skill topic, and an individual checkout session with parent involvement. Participants, two to four college-aged social facilitators, and one to two high school peers attended each group.

Individual Check-in Session

Adolescents first completed an individual check-in session with a college-aged social facilitator. This time period was allotted to provide a private forum to discuss the previous week's social challenges and successes, review social homework, practice self-management of the current individualized target behavior, and become oriented to the activities of the upcoming session. Facilitators used this time to prime individuals of session content and answer questions.

Free Socialization Phase

All participants joined the group's free socialization time with the facilitators and high school peers. This time was allowed to unfold without a predetermined agenda and was intended to create a natural, comfortable social environment. Topics were brought up organically by the participants and often included video games, favorite foods and places to eat, school and current events, vacation and weekend plans, and memorable personal experiences. Food and refreshments were provided for each group to aid in the creation of a casual, club-like atmosphere. While conversing with one another, the participants and social facilitators discretely tracked their use of individual target skills using self-management. The high school peer models and the college-aged facilitators also participated in this self-management process to ensure that every group member was held to the same expectations and to minimize perceived differences between session attendees.

Social Topic Discussion and Practice

After the free socialization phase, the social facilitators then introduced the week's social skill topic, which was explored for the next 40 min. After a brief introduction of the target skill, the topic was then modeled by the social facilitators in a series of two brief role-plays – one “bad” example demonstrating poor implementation of the skill and a follow-up “good” example depicting proper use of that particular skill. Popular television and movie clips were also used to highlight good and bad examples of the skill in question. Social facilitators discussed the main points of the topic and recalled relevant personal experiences. The adolescent participants were also encouraged to contribute to the topic – discussing their experiences related to that topic and providing their own suggestions regarding the successful use of a particular social skill. Finally, for the last 5 min of the group, all participants practiced the related skill with a partner. A manualized curriculum of key points and sample stories and scripts were used to structure and guide these discussions. This portion of the group was intended to increase understanding of a social skills topic and provide opportunities to both observe and practice the skill. Social skills topics covered included making introductions, maintaining a conversation, respectfully disagreeing, and group interactions.

Social Activity Phase

For the final 20 min, the group transitioned into a structured social activity. These activities varied each week, but generally resembled commonly used team-building activities and party games. Activities were also selected to be highly enjoyable and motivating to increase the engagement of the group participants. This phase was intended to foster sharing of personal information, encourage learning about peer interests, increase comfort in the group, and promote cooperation and teamwork. Other benefits included opportunities to work on effective communication, compromise, and good sportsmanship skills.

Checkout Session

At the end of each group session, individual checkout sessions were conducted with each participant, a parent, and their assigned social facilitator. The participants discussed their experiences in the group, reviewed the group socialization topic with their parent, and set two weekly homework assignments – one based on their individual self-management target and the other based on the weekly group curriculum. Finally, a written summary of the current topic was provided to the family as a visual reference.

Efficacy Information

The efficacy of the START program has been evaluated through three peer-reviewed research articles. The first article summarized the results of pilot study with six participants (Vernon et al. 2016). The study used a combination of a multiple baseline and a pre-post design to establish preliminary evidence of efficacy by examining improvements on parent-report measures, adolescent self-report measures, and increases in coded social skill use on videotaped social conversation probes.

A randomized clinical trial was then conducted to evaluate the impact of the START model on social performance. All participants were randomly assigned to one of two groups: Those assigned to the START treatment group immediately received 20 weeks of the START program. Those assigned to the waitlist control group were permitted to continue any preexisting therapy efforts but were not exposed to the experimental socialization treatment package. Both groups were reevaluated after a 20-week time period.

The first START RCT article detailed the results of the parent and adolescent self-report social survey measures (Vernon et al. 2018). Results of the mixed MANOVA analyses revealed the presence of significant Group $\times$ Time effects for the social outcome variables (Wilks' Lambda = 0.53; $F(5,29) = 5.22, p = .002$). Group $\times$ Time interaction reached statistical significance for three outcome measures: Parent SRS, $F(1,33) = 7.68, p = .009$, partial $\eta^2 = .189$; Parent SMCS, F

$(1,33) = 13.29, p = .001$, partial $\eta^2 = .287$; and Adolescent SSIS, $F(1,33) = 7.29, p = .010$, partial $\eta^2 = .181$. All parents endorsed social validity ratings indicating that their adolescent highly enjoyed being a part of the social skills group (mean rating of 8.14 out of 10, $SD = 0.97$). Additionally, they endorsed that their child's social skills and competence improved through participation in the group (mean of 7.50 out of 10, $SD = 0.82$). The adolescent participants also indicated that they enjoyed their time in the groups (mean rating of 8.41 out of 10, $SD = 1.83$). Likewise, they endorsed that their social skills and competence improved through participation in the group (mean of 8.34 out of 10, $SD = 1$).

The next peer-reviewed publication examined real-world social skill use during live peer conversations (Ko et al. 2018). Three observable social behaviors were coded: questions asked, directed positive facial expressions, and mutual engagement. Results revealed a significant Group $\times$ Time interaction effect for Questions Asked, $F(1, 33) = 4.86, p = .035$. Participants in the treatment group significantly increased the percentage of questions asked from pre- to post-intervention, whereas the percentage of questions asked by the waitlist group remained relatively unchanged. Effect size was medium-large (partial $\eta^2 = .128$). Additionally, analyses revealed the presence of a significant Group $\times$ Time effect on the percentage of Positive Facial Expressions, $F(1, 33) = 7.73, p = .009$. The treatment group demonstrated significant improvements in the percentage of directed positive facial expressions during social conversations compared to the waitlist group. The Effect size was large (partial $\eta^2 = .190$). Group $\times$ Time interaction did not reach statistical significance for Mutual Engagement, $F(1,33) = 0.32, p = .576$.

Outcome Measurement

As described above, the efficacy of the START program has been evaluated using standardized survey measures (parent report and adolescent self-report measures; Vernon et al. 2018) and behaviorally coded social skill use derived from

live social conversations with unfamiliar peers (Ko et al. 2018).

Survey-Based Outcome Measures

Social Skills Improvement System Rating Scales (SSIS-RS): The SSIS-RS is a 75–83 item revised version of a widely used rating scale measuring several aspects of social skills, including communication, cooperation, assertion, responsibility, empathy, engagement, and self-control (Gresham and Elliott 2008). Internal consistency alpha reliability coefficients for the parent and self-report forms are reported to be in the mid to upper .90s, with moderate to high correlations to other social and behavioral scales.

Social Responsiveness Scale, Second Edition (SRS-2): The SRS-2 is a 65-item rating scale that covers various dimensions of interpersonal behavior, communication, and stereotypic behavior associated with ASD (Constantino and Gruber 2005). Internal consistency alpha reliability coefficients for the parent forms were reported to be above .90 and strong correlations ($r = .52-.74$) with subscales of the ADI-R. This measure was used as an indicator of ASD symptom severity, with score reductions associated with a decrease in observable symptoms.

Social Motivation & Competencies Scale (SMCS): The SMCS is an unpublished rating scale that was developed by the current researchers for use in this study. It was designed with corresponding parent and adolescent self-report versions. Items pertaining to comfort in social interaction, conversation skill use, empathy, friendships, appropriate behavior, social contact, and social interest were rated on a 5-point Likert scales. This measure was used as an indicator of social motivational factors and concrete skill competencies.

Social Validity Survey: Parents and participants were both asked to provide ratings about the acceptability of the START program. Specifically, they were asked to provide separate ratings on a 0–10 Likert scale on both (a) enjoyment of the adolescent's time in the group and (b) the extent to which the adolescent's social skills and competence improved as a result of participation.

Social Conversation Probe Procedures

Social conversation data were collected during the pre-intervention intake session and after program completion (i.e., after 20 weeks of the START program or waitlist participation). At these time points, participants engaged in 5-min conversations with unfamiliar peers whom they had never met. These peer conversational partners were not trained or coached prior to their interactions with the participants. They also possessed no knowledge of the purpose of the research study and did not know the diagnostic status of the participants. They were randomly assigned to participants and never completed more than one conversation with the same participant. They were provided with the following instructions: "You will be having a conversation with another person that you have never met before. You will have five minutes to get to know each other."

Social Conversation Outcome Measures

Dependent measures were selected to provide representative data associated with improvements to the core social deficits of ASD (APA 2013). Video-recorded conversations, pre- and post-intervention, were systematically coded for each dependent measure. The three dependent measures coded were questions asked, positive facial expressions, and mutual engagement.

Questions Asked: Social inquiries have been identified as a crucial interpersonal strategy, but compared to typically developing adolescents, adolescents with ASD are known to make far fewer social initiations to their peers. A question was defined as a verbal query that is intended to elicit a response from the conversational partner. Trained coders, who were blind to the treatment status of the participants, counted each question asked in the video clips by both the participant and the conversational partner. In order to take into account the number of questions asked by the conversational partner, Questions Asked was defined as the percentage of questions asked by the participant during conversation.

Positive Facial Expressions: Individuals with ASD commonly have deficits in appropriate affective expression. Smiling and laughter have long been established as important

nonverbal indicators of social attunement in conversation and are generally associated with friendliness and positive impressions. Nonverbal social engagement was measured through observed efforts to convey interest in a social partner's conversation (positive facial expressions). A five-second partial interval coding scheme was implemented to code for the presence or absence of a positive facial expression (defined as visible smiling or laughing). A percentage was calculated to determine the percentage of time the participant was displaying positive facial expressions during each 5-min clip.

Mutual Engagement: Challenges with social reciprocity are a hallmark characteristic of ASD. To measure changes in reciprocity, mutual engagement, or the extent to which both social partners were jointly engaging in conversation, was examined to explore the balance of conversational contributions. This measure specifically examined the contributions of a participant relative to their conversational partners. Coders examined five-second intervals and focused on whether (a) the participant was the primary speaker, (b) the conversational partner was the primary speaker, (c) both partners contributed equally to the conversational volley, or (d) no one spoke. Mutual engagement was defined as the percentage of intervals in which both individuals contributed equally to the conversation.

Qualifications of Treatment Providers

Trained undergraduate research assistants served as the social facilitators for the START program. High school volunteers were also recruited from local schools to serve as peer mentors. All facilitators received an initial 10-h training on basic group facilitation techniques, covering basic group facilitation skills, methods for fostering rapport, and exposure to practice group sessions. The social facilitators also participated in weekly 1-h supervision meetings for ongoing clinical training purposes. One undergraduate was assigned as the designated primary social facilitator for each participant and was responsible for all check-in and checkout sessions, along with all progress meetings

with that individual. Advanced clinical psychology doctoral students and a licensed clinical psychologist jointly conducted all training and supervision sessions.

Social Validity

Julia L. Ferguson and Joseph H. Cihon
Autism Partnership Foundation, Seal Beach, CA, USA

Definition

The assessment of social validity involves measures that evaluate the social acceptability of an intervention or program (Kazdin 1977). As it applies to the application of techniques derived

from the science of applied behavior analysis (ABA), the assessment of social validity is defined as measuring the social acceptability of goals, social appropriateness of procedures, and the social importance of the effects of a treatment or intervention (Wolf 1978). Measures of social validity are not meant to be the primary dependent measures of an intervention, nor used to evaluate the effectiveness of a treatment or intervention (Schwartz and Baer 1991). Instead, the measurement of social validity is intended to provide supplemental data to assess the acceptability of an intervention by relevant consumers (Wolf 1978).

Social validity assessment is a two-part process involving (1) obtaining accurate information about consumers' opinions on an intervention or program and (2) using that information to sustain or change an intervention or program (Schwartz and Baer 1991). Based upon this process, there are several ways to assess and measure social validity. Some general techniques to assess social validity are through the use of interviews, questionnaires, surveys, rating scales, discussions with consumers, direct observation, consumer choice of intervention, and comparison of behavior to a normative population (Carter 2010; Schwartz and Baer 1991). Interviews, questionnaires, surveys, rating scales, and discussions are more subjective measures of social validity. Direct observation of behavior, consumer choice of intervention, and comparison of behavior to a normative population are more objective forms of assessing social validity. These methods of measuring social validity may provide data on all three aspects of the social validity of an intervention that Wolf (1978) outlined (i.e., goals, procedures, effects) or only one or two aspects of an intervention (e.g., assessing the social validity of the treatment effects). Selecting the consumer who will respond to assessments of social validity (e.g., interviews, surveys) is another important aspect of the social validation process. Consumers who could be asked about the social validity of an intervention could be direct consumers (i.e., the individual participating in the intervention), indirect consumers (i.e., those individuals who are strongly impacted by the intervention), members

of the immediate community (i.e., individuals who interact with either direct or indirect consumers), or members of the extended community (i.e., those who live in the community with the direct or indirect consumers; Schwartz and Baer 1991).

Historical Background

ABA is the scientific application of the principles of behavior analysis to socially significant problems, as was defined by the authors of the first seminal article in the *Journal of Applied Behavior Analysis* (JABA; Baer et al. 1968). Within this seminal article, the authors outlined seven dimensions of the science of ABA; the first two described being applied and behavioral (Baer et al. 1968). To uphold the applied dimension of ABA the authors stated that the science would address problems that are socially significant to society. To uphold the behavioral dimension of ABA, our science seeks to change behavior that is observable and measurable. Baer et al. (1968) stated that the behavioral dimension was of critical importance to the science of ABA and urged the field to avoid the use of subjective measures of behavior, such as verbal reports of behavior and feelings. Since ABA is a science of behavior, Montrose Wolf understood the importance of observable and measurable behavior and grew concerned as the editors of JABA began to publish studies which included subjective measurements in addition to objective and measurable changes in behavior (Wolf 1978). But, as the journal progressed, more and more publications included subjective measures (Wolf 1978). Wolf grew concerned but found solace in the applied dimension of ABA. If the goal of JABA was to publish studies that address problems of social importance, how would the field decide which behaviors, procedures, and results were socially important to the consumers? Wolf noted that in order for ABA to uphold the applied dimension of our science, behavior analysts would need to use subjective measurement to assess social validity (Wolf 1978). In 1987, Baer, Wolf, and Risley wrote another seminal paper entitled “Some still

current dimensions of applied behavior analysis” which reiterated the seven dimensions outlined in 1968. In this paper, social validity was mentioned several times as a way to evaluate if ABA, as a science, is supporting the dimensions of practice. The authors further stated, having “valid social-validity assessments will soon become crucial to survival [of our science]” (Baer et al. 1987, p. 323).

Current Knowledge

Currently, there have been two literature reviews assessing the use of social validity within JABA. Kennedy (1992) analyzed articles published in JABA from 1968 to 1990 and articles published in *Behavior Modification* from 1977 to 1990 for the frequency and types of social validity measurements used within the two journals. Kennedy found that the measurement of social validity rarely occurred within JABA between the years 1968 and 1975, but increased in the mid-1970s. The measurement of social validity within JABA peaked in 1983 and then decreased to a steady rate (i.e., 20% of articles reporting social validity measures) throughout the late 1980s. Similar trends in the journal *Behavior Modification* were also found. Carr et al. (1999) extended Kennedy’s work and evaluated social validity trends in JABA through 1998 (Carr et al. 1999). Carr et al. found similar trends through the 1990s, with approximately 25% of articles published in JABA reporting measures of social validity. Taken together, the results of these reviews show that there has been a lack of research reporting social validity measures within behavior analytic research.

Research on the process of social validity has mainly focused on how to assess the social appropriateness of behaviorally based treatments (Carter 2010). The majority of the research on this process has occurred around the development and evaluation of the Treatment Evaluation Inventory (TEI; Kazdin 1980). The TEI has 16 items which are rated on a Likert type scale from 1 to 7 (Kazdin 1980). Originally, this tool was evaluated with 88 participants and each participant was

given case descriptions which she/he then rated using the TEI. Kazdin found that when several different treatment scenarios were described to the evaluators, they rated the interventions differentially across several aspects including questions about how likely they would be to implement the treatment, how unfair they thought the treatment was, and how acceptable they thought the treatment was for the participants. Analyses were conducted in order to evaluate the strength of the relationship between the acceptability ratings and the treatment scenarios (Kazdin 1980). The TEI was found to account for 61% of the differences in the acceptability ratings across treatments and the author concluded that the strength of the treatment effect was relatively large (Kazdin 1980). The TEI has the most research to support the validity of its use and continues to be evaluated and utilized today (e.g., Diller et al. 2013).

Future Directions

Given the paucity of research on the assessment of social validity, the future directions are not that different from those outlined by Schwartz and Baer in 1991. Schwartz and Baer (1991) stated that the future directions of social validity were threefold, and these directions are still applicable today. First, more researchers and clinicians need to conduct social validity assessments and report the results. Based upon previous reviews, social validity measures within research published in JABA has been reported in about 20% of articles across the past 30 years (Carr et al. 1999; Kennedy 1992). Furthermore, these reviews found that the overall trend of articles publishing measures of social validity is not increasing in our flagship journal (i.e., JABA). Even though the probability of research published in JABA reporting social validity measures is low, it may not mean research within the treatment of ASD as a whole is not. JABA is a small sample with respect to research conducted on the treatment of ASD. In addition to striving to increase the assessment and reports of social validity within research, behavior analysts could also measure

and report social validity measures in our clinical practice and report the findings outside of research journals.

The second future direction stated by Schwartz and Baer (1991) was that a greater number and types of consumers should be asked to report on social validity. Currently, direct consumers and indirect consumers closely involved with the participants of the intervention are the ones commonly involved in the assessment of social validity. Less commonly included consumers are members of the immediate and extended community. Including immediate and extended community members in the assessment of the social validity of our interventions could have potential benefits for how our science is perceived by others and how our procedures become mainstream (Friman 2014).

Third, Schwartz and Baer (1991) suggested that future research on the topic of social validity should evaluate objective precursors associated with the social invalidity and validity of a program. This suggestion remains relevant today. More research is required evaluating the predictors of the social validity or invalidity of a program or intervention because the effectiveness of an intervention is not enough for the widespread adoption of behavior analytic programs. The lack of the adoption of Direct Instruction within public schools after the program was evaluated through Project Follow Through (Lindsley 1992; Morrell 1998; Watkins 1997) is a prime example. Although Direct Instruction and the behavior analytic teaching models were found to be the most effective forms of education, these procedures were not adopted by the schools and the procedures are rarely implemented by teachers (Watkins 1997). Why would these procedures not be adopted and widely used if they were proven to be the most effective? One reason is that the social acceptability of these procedures was not initially assessed. Assessing the social validity of Direct Instruction prior to nationwide implementation could have provided much needed information on how the model was perceived by teachers, administrators, and students. Stallings (1974) found that the teachers who implemented Direct Instruction were the least satisfied with the program. This critical information

could have been utilized to inform improvements to increase the social acceptability of Direct Instruction. The assessment of social validity is vital to the survival of our science. To date, there continues to be a lack of reporting on social validity measures within applied behavior analytic research. If the techniques derived from our science are to become a mainstay of our society, we need to increase both the assessment and reporting of social validity measures.

³Department of Pediatrics, University of Alberta, Autism Research Centre, Glenrose Rehabilitation Hospital, Edmonton, AB, Canada

Definition

Social-emotional (SE) development refers to the capacity to experience, express, and manage one's emotions, as well as the ability to understand and respond to the emotional states of others. In the first few years of life, children rapidly develop social and emotional competencies that allow them to navigate increasingly complex social interactions, including establishing and maintaining relationships with others. These skills are important contributors to emotional well-being and psychological health in adulthood (Frijda 1986; Ekman 1992; Saarni et al. 2006). Many of these SE skills, however, are challenging for children with autism spectrum disorder

(ASD). That is, children with ASD often experience difficulties in SE reciprocity – such as emotional expressiveness, regulation, and responsiveness – contributing to their difficulties in engaging appropriately in social situations (American Psychiatric Association 2013; Sigman and Capps 1997).

Emotional and social development are intertwined and affect how one makes social connections and responds to others (Frijda 1986; Ekman 1992; Saarni et al. 2006; Darwin et al. 1998; Shariff and Tracy 2011; Cole and Moore 2015). Emotions can be understood as dynamic, social processes, both created by and resultant from social relationships with others (Salovey 2003). During typical development, the expression of emotions is regarded as the first social-communicative action of infants, with important implications for later competence. For example, emotional expressiveness in infancy evokes responses from caregivers and invites them to share emotional states, resulting in SE reciprocity. By the second year of life, intentional communication skills develop, allowing toddlers to engage in more complex SE behavior to share experiences with others (Mundy 1995). As infants and toddlers are particularly attuned to social and emotional stimulation early in life, the degree of scaffolding and responsiveness by caregivers help to regulate these emotions and greatly impact subsequent SE growth and development (Carter et al. 2004; Feldman 2007).

SE capacities develop from both intra- and interpersonal processes. Intrapersonal SE behavior includes the ability to identify and understand one's own emotions, to manage and communicate emotions, and to regulate one's own behavior. Interpersonal aspects of SE behavior involve the ability to accurately identify and interpret the emotional states of others, as well as the capacity to empathize (Harris 1989; Frith 1994; Denham 1998; Thompson and Lagattuta 2006). In building these SE skills, children are learning how to establish and maintain relationships with family, peers, and the community to promote successful participation in reciprocal social interactions and navigation of complex social environments (Skinner 2018).

Historical Background

Difficulties in SE and affective behavior have been noted in Leo Kanner's (1943) original observations of 11 cases of autism, where he defined ASD as a biological impairment in the capacity for social relatedness. Kanner described children with ASD as "hav[ing] come into the world with innate inability to form the usual, biologically provided affective contact with people, just as other children come into the world with innate physical or intellectual handicaps." He noted that these children were emotionally detached, aloof, and unresponsive – many of whom were unable "to relate themselves in the ordinary way to people and situations from the beginning of life." Kanner's (1943) original account highlights the role of SE behavior in the emerging ASD phenotype, pointing to a failure of mechanisms to perceive, express, respond to, and understand social and emotional events.

Evidence of the ASD-related SE impairments in ASD is largely confined to retrospective parental reports and early home video review due to the later age of diagnosis (still at the age 4–5 mark; Brett et al. 2014; Christensen et al. 2016). As many as 50% of parents recall SE difficulties within the first year of life, including marked displays of temperament and behavioral reactivity and lack of responsiveness to attempts of social interaction and play (Ohta et al. 1987; Dahlgren and Gillberg 1989; De Giacomo and Fombonne 1998). Moreover, during the second year, parents have retrospectively reported a pattern of regression involving loss of speech and/or SE connectedness in approximately 20–50% of children with ASD (Kurita 1985; Hoshino et al. 1987; Rutter and Lord 1987; Werner and Dawson 2005). Similarly, analyses of early home videotapes have revealed that children later diagnosed with ASD show atypical emotional development around the time of their first birthday. Findings include increased negative affect, ambiguous emotional expressions, and atypical affect regulation (Adrien et al. 1991; Baranek 1999; Maestro et al. 2005).

Current Knowledge

Early difficulties in SE behavior play a role in the emerging phenotype of ASD. Many of the first studies examining SE development in children with ASD have focused primarily on emotional expressiveness and responsiveness. These retrospective studies indicated that although children with ASD did not appear less emotionally expressive than children with typical development (TD) or mental retardation (Ricks and Wing 1975), they did experience higher levels of negative emotions and lower levels of positive emotions (Capps et al. 1993). Other studies investigated whether emotional expressions and responses of children with ASD were socially and contextually appropriate. Compared to children with TD or mental retardation, children with ASD showed deficits in emotional expression and sharing of emotional experience, such as reduced positive affect and coordination of gaze with emotion expression to share experiences (Yirmiya et al. 1989; Kasari et al. 1990, 1993). Furthermore, prospective studies of children later diagnosed with ASD have noted that the paucity of SE reciprocity, combined with delays in verbal and non-verbal communication, contributes to increased negative affect and distress, reduced positive affect, and low levels of regulation (Gomez and Baird 2005; Zwaigenbaum et al. 2005; Bryson et al. 2007; Clifford et al. 2007; Watson et al. 2007; Garon et al. 2009, 2016). These atypicalities are apparent in the first years of life of children who go on to be diagnosed with ASD, with upward of 30% of parents reporting SE concerns by their child's first birthday (De Giacomo and Fombonne 1998; Sacrey et al. 2015).

The recent application of prospective studies of infant siblings of children diagnosed with ASD, the so-called "high-risk" sibling (having a higher probability of also being diagnosed with ASD, at about 18% (Ozonoff et al. 2011), compared to the general population at 1–2% (Baio et al. 2018)) has allowed a more in-depth examination of SE behavior as it develops. A large study of

331 high-risk infant siblings and 133 infants of families without a history of ASD used the Infant Toddler Social-Emotional Assessment (ITSEA; described below) to collect information on SE behavior when the children were 18 months of age (Raza et al. 2019). The HR infant siblings who were diagnosed with ASD at age 3 showed a higher prevalence of internalizing (depression, anxiety) and dysregulation (negative emotionality) concerns and a lower number of competencies (empathy, prosocial peer relations) compared to other high-risk infant siblings who were not diagnosed with ASD and comparison infants. Furthermore, these behaviors at 18 months were associated with total severity scores on the Autism Diagnostic Interview and the Autism Diagnostic Observation Scale at age 3 (Raza et al. 2019). Using a Brief version of the ITSEA (BITSEA; described below), Kiss et al. (2017) compared SE behavior in preschool children with and without ASD and developed three new scales for use in ASD screening (the ASD Problems, ASD-Competence, and ASD-Total subdomains). The ASD-Competence scale best discriminated ASD from TD and other developmental delays (0.91 for sensitivity, 0.80 for specificity).

In line with these findings, examination of SE behavior in school-aged children diagnosed with ASD also highlight the higher prevalence of SE atypicalities compared to TD peers. Intellectually delayed children with ASD have more neutral or idiosyncratic expressions (e.g., smiling when not appropriate to the context) compared to TD peers (Capps et al. 1993) and a higher prevalence of emotional disorders than children with an intellectual disability without ASD (71% vs. 42% for emotional problems and 65% vs. 46% for conduct problems, respectively; Totsika et al. 2011). In contrast, intellectually able children with ASD show a similar range of expressiveness as TD peers, yet they also display less positive affect (Capps et al. 1993) and have higher levels of emotional problems (74% vs. 18%, respectively) and conduct problems (64% vs. 22%, respectively) than their TD peers (Totsika et al. 2011).

Impaired SE behavior has been implicated in a range of co-occurring and/or comorbid problem behavior in children with ASD. It is estimated that up to 50% of children with ASD meet clinical criteria for two or more SE disorders, even after controlling for the social-communication and repetitive behavior/restrictive interest core diagnostic criteria (Leyfer et al. 2006; Simonoff et al. 2008). Depression and anxiety are often reported to be the most frequent SE comorbid diagnosis (Howlin 2000). A recent meta-analysis (Lugo-Marin et al. 2019) of 47 studies examining the prevalence of SE disorders in adults with ASD found that 18.8% were also diagnosed with a mood disorder (depression and bipolar most prevalent), 17.8% were also diagnosed with an anxiety disorder (social anxiety disorder, obsessive compulsive disorder, and adjustment disorder most prevalent), and 54.8% were diagnosed with any psychiatric disorder (including substance use disorder, schizophrenia spectrum disorder, mood disorder, anxiety disorder, eating disorder, personality disorder, and attention deficit hyperactivity disorder).

Thus, it is fitting that deficits in SE reciprocity are included in the diagnostic criteria of ASD in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association 2013) and the International Classification of Diseases-11 (World Health Organization 2018). Because SE impairments appear early in life and impact developing social and language skills (Carpenter and Tomasello 2000; Mundy and Sigman 2006; Woods and Wetherby 2003), assessment tools that probe behaviors characterizing ASD, such as the Autism Diagnostic Interview-Revised (ADI-R; Rutter et al. 2003) and the Autism Diagnostic Observation Scale-2 (ADOS-2; Lord et al. 2000), also include probes for SE behavior.

Measuring Social-Emotional Behavior

Over the past few decades, researchers have emphasized the importance of identifying young children at risk for delays in SE behavior. To fully understand SE development in infants and

toddlers, assessments of both problem behavior and competencies are crucial (Briggs-Gowan and Carter 1998; Carter et al. 2003; Carter and Briggs-Gowan 2006). Competencies include behavior that reflect achievement of age-appropriate skills in SE development – such as attention, empathy, emotional awareness, and prosocial peer interactions, to name a few (Radke-Yarrow and Zahn-Waxler 1984; Saarni 1988; Eisenberg and Mussen 1989; Zahn-Waxler et al. 1992; Briggs-Gowan and Carter 1998). Assessments of SE competencies are important for understanding a child's ability to meet new developmental demands, the likelihood of later competence, and the risk for subsequent SE difficulties (Denham et al. 1990; Cicchetti 1993; Cicchetti and Cohen 1995; Hay et al. 1995; Masten and Coatsworth 1995, 1998; Carter 2002). SE problems, on the other hand, are comprised of behavior that reflects a failure to achieve age-appropriate SE competencies and may interfere with aspects of a child's functioning. This includes behavior that occurs in TD but has become problematic (i.e., atypical expression, frequency, and/or intensity), as well as behavior that deviates from the normative developmental course. Behavior traditionally characterized as externalizing and internalizing problems (Achenbach 1966), regulatory problems, and maladaptive behavior encompass SE problems (Briggs-Gowan and Carter 1998; Carter et al. 2003; Carter and Briggs-Gowan 2006).

With these constructs in mind, the ITSEA and BITSEA were developed to measure SE behavior in young children. The ITSEA is a parent-reported questionnaire for children between 12 and 36 months of age that profiles problem behavior and competencies (Carter and Briggs-Gowan 2006). The ITSEA is comprised of 190 questions querying four domains of SE behavior: externalizing (e.g., aggression), internalizing (e.g., anxiety), dysregulation (e.g., negative emotionality), and competence (e.g., empathy). The ITSEA was shortened to the BITSEA (Briggs-Gowan and Carter 2002). This version is comprised of 42 questions covering SE problem behavior and competencies, as well as a new ASD domain that

is designed to identify children with SE difficulties that may require additional follow-up for ASD.

Other assessments that are not specific for SE behavior but have been used to collect information on SE development and related atypicalities include the Battelle Personal-Social Domain (Newborg et al. 1984), the Child Behavior Checklist (CBCL2/3; Achenbach et al. 1987), the Infant-Toddler Developmental Assessment (IDA; Provence et al. 1995), the Toddler Behavior Checklist (Mouton-Simien et al. 1997), and the Vineland Adaptive Behavior Scales (VABS; Sparrow et al. 1984).

Future Directions

Substantial progress has been made in the conceptualization of SE development in children with ASD. Growing evidence suggests that impairments in SE development may limit functional outcomes for children with ASD and give rise to a range of co-occurring and/or comorbid problem behavior (Gadow et al. 2004; Brereton et al. 2006; Witwer and Lecavalier 2008). Up to 50% of children with ASD meet clinical criteria for two or more SE disorders, the underpinnings of which appear very early in childhood (Raza et al. 2019; Kiss et al. 2017). As such, early detection of emerging SE atypicalities is warranted to promote healthy developmental outcomes and successful school adaptation.

To this end, a greater emphasis on exploring the associations between SE behavior and ASD symptom presentation is crucial. Investigating this relationship can improve our understanding of the mechanisms underlying ASD etiology, phenotypic overlap between core diagnostic symptoms, and comorbid psychopathologies, as well as clarify the role SE development plays in functional outcomes of individuals with ASD. This may contribute to early identification and diagnosis of ASD and inform the development of SE interventions and treatment approaches, with broader implications for

policies and mental health services that aim to improve the quality of life for individuals with ASD.

What can we do to achieve these goals? Adequately powered longitudinal studies are needed to elucidate how SE atypicalities increase the risk of comorbid psychiatric disorders and outcomes in individuals with ASD. Additionally, cohort studies following both high-risk infants and early diagnosed children into adolescence and beyond may provide a clearer picture of SE trajectories, as well as identify clusters of behaviors that are predictive of specific comorbid diagnoses (e.g., anxiety, ADHD). Finally, integrating information across several methodologies and assessments (i.e., combinations of behavioral observation, physiological measurement, and parent-report) could provide a holistic picture of SE processes to promote healthy development and positive mental health and establish a strong foundation for school readiness and future success.

²Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, USA

³Department of Psychiatry, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

Definition

The term “inhibition of return (IOR)” refers to a cognitive mechanism that biases visual attention against previously explored locations in order to favor exploration of new areas. “Social-emotional IOR” specifically refers to alterations in the IOR mechanism by social-emotional cues, in that the saliency of such information is hypothesized to capture and hold attention to a greater degree, thus diminishing the IOR effect in the neurotypical population.

Historical Background

Visual attention is one modality in which individuals navigate their world and learn from it. Social-emotional signals are prioritized in visual orienting from an early age in neurotypical children, as this information can capture and hold attention to a greater degree than other information due to its saliency (Johnson et al. 1991; Klin et al. 2002; Nakano et al. 2010; Riby et al. 2012; Rice et al. 2012; Yerys et al. 2012). Multiple processes comprise visual attention, including the orienting process, which allows for disengagement, shifting, and reengagement of attention (Posner and Petersen 1990). The IOR mechanism specifically reflects an adaptive bias in visual

attention orienting, such that previously inspected spatial locations are inhibited in order to prioritize exploration of novel spatial locations. Further, this mechanism has been linked to facilitation of visual search, with alterations in IOR resulting in repetitive search of already inspected areas (Itti and Koch 2001; Klein 2000; Tipper et al. 1996; Wang and Klein 2010). Salient information, such as social-emotional cues, can override or diminish the IOR effect in order to prioritize this type of information for processing (Fox et al. 2002).

The IOR effect can be elicited and measured using a peripheral spatial cueing task in which participants are first presented with a cue (e.g., a flashing box or picture of a face to the left or right of center) followed by a target (e.g., an asterisk ‘*’) on either the same (Valid) or opposite side (Invalid) of the cue’s original location (Fig. 1). Previous work has demonstrated that the IOR effect is apparent when the interval between the cue and target (cue-target onset asynchrony; CTOA) is longer than 300 ms, such that participants make slower manual responses to validly cued trials than invalidly cued trials (IOR effect = Valid response time – Invalid response time; Posner et al. 1984).

Fox et al. (2002) demonstrated that angry schematic faces diminish the IOR effect in neurotypical young adults, such that the difference in response time between the validly cued trials and invalidly cued trials for angry faces is less than that for neutral faces. Similar findings have been replicated with ecologically valid social-emotional face cues (Pérez-Dueñas et al. 2014) and other nonsocial emotionally evocative cues (i.e., spiders, emotionally valenced words; Pérez-Dueñas et al. 2009; Rutherford and Raymond 2010). Further, greater anxiety and worry traits have been linked to a diminished social-emotional IOR effect (Verkuil et al. 2009). There is mixed evidence as to whether social-emotional signals diminish IOR (Stoyanova et al. 2007), though these conflicting results may be driven by task variability, which has been

Social-Emotional Inhibition of Return, Fig. 1 Peripheral spatial cueing paradigm. This paradigm is used to measure the IOR effect. Two trial types are depicted here: (a) Valid trials in which the cue and target appear on the same side and (b) Invalid trials in which the cue and target appear on opposite sides. CTOA and stimuli type may vary

demonstrated to influence the presence of the IOR effect when using social-emotional cues (Silvert and Funes 2016). As social-emotional cues may capture attention to a greater degree, making it difficult to inhibit and disengage from, the use of social-emotional cue stimuli in a spatial cueing paradigm provides an opportunity to test how this type of information may be prioritized via the IOR effect in visual attention orienting.

Current Knowledge

Altered visual attention has been frequently reported in ASD (Keehn et al. 2013; Sacrey et al. 2014), which may be linked to the noted strengths (i.e., attention to detail; Happé 1994; Mottron et al. 2006) and weaknesses (i.e., diminished social attention; Klin et al. 2002; Riby et al. 2012) in this condition. Visual orienting is one of the mechanisms proposed by the social motivation hypothesis to contribute to the cascading difficulties in reciprocal social communication in ASD over the lifespan (Chevallier et al. 2012; Clements et al. 2018). For example, seminal work by Swettenham et al. (1998) using a naturalistic task found that 20 month old infants with ASD demonstrated more shifts between objects and less spontaneous shifts toward faces compared to both typically developing infants and infants with developmental delay. These reports of atypical visual orienting have been replicated with spatial attention tasks (i.e., gap overlap tasks), such that when compared to controls, infants at high-risk for developing ASD, youth with ASD, and adults with ASD have demonstrated difficulties orienting toward social stimuli compared to controls (Elsabbagh et al. 2009; Kikuchi et al. 2011; Landry and Bryson 2004; Sacrey et al. 2013; Zwaigenbaum et al. 2005). Considering the visual attention strengths in ASD, the social impairments that characterize ASD, and the important role that social-emotional information has on visual attention, measuring IOR with social emotional cues can aid in understanding the prioritization of this type of information in ASD.

To date, six studies have examined IOR in ASD, with two out of six studies using peripheral social or emotional cues (Antezana et al. 2015;

Zalla et al. 2016) and four out of six studies using peripheral simple visual cues (i.e., flashing box; Marotta et al. 2013; Pieron et al. 2014; Rinehart et al. 2008; Song et al. 2018). Of note, one study additionally used central social cues to measure IOR (Marotta et al. 2013).

In regards to IOR with simple nonsocial visual cues, Rinehart et al. (2008) were the first to explicitly test the IOR effect in ASD using a spatial cueing task with peripheral cues (i.e., gray rectangle that flashed white) in 12 children with autism without intellectual disability, 12 children with Asperger's syndrome, and 12 typically developing controls. Although the autism and control groups exhibited similar IOR effects, the Asperger's syndrome group trended towards a stronger IOR effect compared to the control group, demonstrating that the IOR effect may capture a potential alteration in visual attention orienting in ASD. Marotta et al. (2013) examined the IOR effect in 14 children with Asperger's syndrome compared to 14 typically developing controls using peripheral visual cues (i.e., a flashing '+' sign) and central eye gaze cues. No group differences were found in IOR for peripheral visual cues, but the autism group demonstrated absence of IOR for central eye gaze cues, in that they responded faster to gaze valid stimuli than gaze invalid stimuli (Marotta et al. 2013). IOR in the original spatial cueing task (Posner et al. 1984) is only measured with peripheral cues, not central cues, thus it is difficult to compare IOR in this context to results from other studies.

When testing multiple CTOAs with a spatial cueing task, one study found a stronger IOR effect emerged for adults with ASD compared to controls at 200 and 300 ms CTOA, but no group differences at 500 and 700 ms CTOA (Pieron et al. 2014). Thus, suggesting an accelerated time course for IOR in ASD, which may be linked to the superior search abilities noted in ASD (Mottron et al. 2006). A recent study by Song et al. (2018) examined visual IOR in 16 children with ASD and 16 typically developing controls; contrary to previous findings of null group differences (Marotta et al. 2013) or potentially stronger IOR effects in ASD (Pieron et al. 2014; Rinehart et al. 2008), they found that the ASD group demonstrated a diminished IOR effect compared to the control group.

Extending findings of potential alterations in visual IOR for ASD, Antezana et al. (2015) examined social-emotional IOR using peripheral neutral and angry face cues in 41 children with ASD and 25 typically developing children. Although there were no group differences for Angry IOR versus Neutral IOR, findings of a stronger IOR effect for all social-emotional cues emerged for the ASD group compared to the control group. Thus, the ASD group took a greater amount of time in responding to valid social-emotional cues (i.e., area was inhibited for longer) than invalid social-emotional cues, indicating presence of an orienting alteration. Interestingly, IOR was specifically linked to ASD symptomology, such that those with a stronger IOR effect also demonstrated greater ASD symptomology. The IOR effect was not linked to anxiety or ADHD symptomology.

Zalla et al. (2016) examined IOR in 16 adults with autism and 16 controls who were matched on age, gender, IQ, and educational level. In this study, the authors used inverted versus upright face stimuli, with averted gaze faces as peripheral cues, and semitransparent gray squares over the face stimuli as targets. They found that both groups demonstrated an IOR effect to the inverted face condition, though the ASD group displayed diminished IOR for the upright face condition. As gaze cues were used, this alteration may be linked to reflexive exogenous orienting in ASD, which are important for development of social skills, i.e., joint attention (Dawson et al. 2004).

Currently, a number of studies point to potential alterations in the magnitude and timing of visual IOR in ASD (Pieron et al. 2014; Rinehart et al. 2008; Song et al. 2018), with accumulating evidence for social and emotional cues playing a role in alterations of the IOR effect in ASD (Antezana et al. 2015; Zalla et al. 2016). Future work is needed in understanding both the task variability (i.e., CTOA, cue and target stimuli type) and developmental contexts (i.e., age), which may influence IOR in ASD.

Future Directions

As there is some evidence for alterations in the IOR mechanism in ASD, it is important for future

work to disentangle the role of social-emotional cues (and other cue types) on the IOR effect across development. Examining the IOR effect with social-emotional cue types within typical and atypical development may reveal critical periods for orienting, which may have cascading effects on social outcomes in ASD. Currently, no studies exist examining the IOR effect longitudinally or cross-sectionally to uncover developmental trajectories or age differences in IOR. In ASD, IOR has been mostly examined in youth (Antezana et al. 2015; Marotta et al. 2013; Rinehart et al. 2008; Song et al. 2018), though two studies have examined the IOR effect in adults (Pieron et al. 2014; Zalla et al. 2016). The mixed findings in directionality of magnitude may partially be related to differences in age of samples; for example, a stronger IOR effect has been found with social-emotional cues in youth with ASD (Antezana et al. 2015), while diminished IOR with social gaze cues in adults with ASD (Zalla et al. 2016). Future work examining the IOR effect developmentally can aid in understanding of risk and resilience factors for social outcomes in ASD.

It is known that task variability influences whether an IOR effect is evoked with social-emotional cues (Silvert and Funes 2016), thus it will be important to understand the task contexts in which IOR is altered for ASD. More specifically, CTOA, stimuli type, and whether peripheral or central cues are used may greatly influence the magnitude of an IOR effect and whether group differences exist. As one study in adults found that the ASD group had an accelerated onset for IOR compared to controls (Pieron et al. 2014), examining multiple CTOAs may be important in understanding the IOR mechanism in ASD. Currently, only a few studies have examined multiple CTOAs in ASD (Pieron et al. 2014; Rinehart et al. 2008; Song et al. 2018), while others have used a fixed CTOA across the task (Antezana et al. 2015; Marotta et al. 2013; Zalla et al. 2016). Future work can examine whether this accelerated onset is also present with social-emotional cue types and across development.

Task variables such as the spatial location of cues and type of stimuli used in the spatial cueing task may further impact the magnitude of IOR

effect in ASD. For example, visual orienting is differentially affected by peripheral versus central cues (Posner and Cohen 1984). Although most of the work examining the IOR effect in ASD has used peripheral cues, there is a potential for a diminished IOR effect in ASD when using central social gaze cues (Marotta et al. 2013), though more work is needed in this area.

The type of stimuli used as cues and targets may further influence orienting based on saliency and valence. For example, the use of salient versus simple visual *targets* (i.e., face vs. ‘*’) may impact the rate of return to inhibited areas. In regard to cues, simple nonsocial visual stimuli (i.e., flashing square) have been primarily used in ASD, though more work is needed in understanding how the complex social, nonsocial, and emotionally evocative stimuli impact the IOR effect. Currently, there is use of social gaze and social-emotional cues, though these cue types may have distinct influences on IOR for ASD, as the former relates to social information processing, while the latter relates to threat-based processing. Additionally, as there is evidence that nonsocial information is prioritized over social information in ASD (Bos et al. 2019; Kohls et al. 2018; Sasson and Touchstone 2013), it will be important for future work to examine the IOR effect with positively valenced nonsocial images (i.e., restricted interest or object stimuli) which autistic individuals may find harder to disengage from. Moreover, considering the high rates of anxiety disorders (i.e., phobias, social anxiety) in ASD (Lai et al. 2019), the use of negatively valenced emotionally evocative stimuli (i.e., spiders, angry faces) with the peripheral spatial cueing paradigm can unveil how orienting mechanisms may be altered in relation to co-occurring anxiety symptoms in ASD. The peripheral spatial cueing paradigm can be extended to examine how the saliency of different types of information may impact prioritization of information via orienting in ASD.

Eye-tracking can reveal more granular IOR effect results than manual responses. This type of methodology can measure how long information was visually inhibited versus current methods of response time only allowing for processing speed of the target. Additionally, as repetitive

foraging has been suggested as being a failure of IOR effect, eye-tracking can elucidate as to whether alterations in IOR are due to repetitive orienting toward inhibited areas or delayed orienting overall. Finally, examining how the IOR effect interacts with visual search capabilities in ASD can further aid in understanding the perceptual strengths in ASD. If alterations in IOR exist for ASD, it will be useful to examine linkages of these effects with other cognitive and social outcomes across development to reveal potential markers for risk.

Altogether, current work suggests that potential alterations in IOR exist, with magnified effects with social and emotionally evocative cues (Antezana et al. 2015; Marotta et al. 2013; Zalla et al. 2016), future work is needed in disentangling task effects, such as CTOA, stimuli type for cues and targets, and the role of peripheral and central cues on the IOR effect. Eye-tracking methods may reveal fine-grained behavioral patterns that lead to group differences. It is important for future work to examine the IOR effect as it relates to cognitive and social outcomes to understand how alterations in this mechanism are linked to strengths and weaknesses in ASD across development.

Definition

The processes related to acquisition of social skills high-functioning autism include contributions from theory of mind, executive functioning, and pragmatics.

Historical Background

Literature shows the persistent difficulties in communication and social interaction experienced by children with autism spectrum disorder (ASD) across multiple contexts. They affect a large number of children with ASD, to the extent that 87% and 47.8% of them score in the borderline/abnormal range on scales measuring respectively peer problems and prosocial behavior (Helland and Helland 2017). The impairments are expressed in behaviors such as inappropriate affect, social isolation, and failure to initiate interactions with peers, cooperate, share, make friends, express empathy, or provide emotional support (Russell et al. 2012; Schwenck et al. 2012). These social disabilities may cause daily difficulties, become more pronounced with age, and can lead to negative long-term outcomes. Despite these significant social and communication challenges, scant empirical research has been dedicated to the study of the variables mediating socialization impairments in children with high-functioning autism (HFA).

Different sources of social communication deficits in ASD have been proposed. One of the most known explanations refers to “theory of mind” (ToM) deficits, which implies difficulties

being aware that others have a mind with mental states, information, and motivations that may differ from one’s own (Baron-Cohen 1995). Therefore ToM allows an individual to effectively communicate and interact socially. Individuals with ASD obtain significantly worse results on ToM measures than people with typical development (TD) (Baron-Cohen 1989), and the lack of ToM competences in children with autism impairs their social behaviors (Mazza et al. 2017). In particular, Bishop-Fitzpatrick et al. (2017) determined that performance on first- and second-order false belief tasks was significantly associated with better social functioning, materialized as higher levels of socially adaptive behavior and lower levels of social problems. Nevertheless, it is important to underline the inconsistent results found in research, with some studies failing to detect significant associations between ToM and social functioning (Jones et al. 2017).

Pragmatic competence (PC) has also been linked to social problems in ASD. Pragmatics is defined as the range and frequency of communicative functions, discourse skills, and flexibility to modify speech for different listeners and social situations. It requires picking up cues from the language and behavior of others and an understanding of the rules which govern behaviors in context. Deficits in pragmatic skills are highly prevalent in individuals with ASD, especially in domains related to discourse management (skills to start, maintain, and end a conversation, taking turns, prosody), conversational repairs, and presuppositions (assumptions about the speaker and the specific social context, ToM) (Schoen Simmons et al. 2014). Compared to their peers with TD, they use fewer facial expressions and gestures, have difficulty taking turns in conversation, and can insist on topics in which they are especially interested. The structural language and pragmatics abilities have been related to social functioning in children with ASD, contributing with significant unique variance to the prediction of social behavior (Volden et al. 2009). Moreover, children and adolescents with HFA with more social symptoms of autism have been reported to present lower performance on pragmatic

competence measures (Orinstein et al. 2015). These pragmatic deficits affecting social relations tend to persist in adolescence and adulthood and lead to feelings of loneliness and social exclusion.

Other potential source of the social difficulties encountered by individuals with ASD is the deficit in executive functioning (EF). Executive functions encompass a broad spectrum of inter-related processes that are in charge of “guiding, directing, and controlling cognitive, emotional, and behavioral functions, especially during the active solution of novel problems” (Gioia et al. 2000). The role of the executive profile in autism requires more thorough analysis, but research have suggested a specific pattern of executive dysfunction in components such as planning and flexibility that distinguishes autism from other disorders (Hill 2004; Wallace et al. 2016). A review of the relationships between EF and the social domain of impairment in ASD revealed inconsistent results (Jones et al. 2017). Some studies failed to report significant relations (Cantio et al. 2016), but other investigations pointed out that poorer EF is associated with increased playground isolation and less engagement with peers (Freeman et al. 2017). Moreover, significant associations and longitudinal predictive power have been found between sub-domains of the Behavior Rating Inventory of Executive Function (BRIEF) and adaptive functioning on the Vineland Adaptive Behavior Scales, with executive problems significantly contributing to less adaptive behavior across domains (Pugliese et al. 2015). In addition, the executive functions have demonstrated to predict both emotional and behavioral school engagement, and more specifically, emotion regulation has predicted prosocial peer engagement (Jahromy et al. 2013). Studies have also shown that the pattern of associations between adaptive social behaviors and the EF is different in ASD compared to TD (Leung et al. 2016). The executive processes of behavioral regulation, including inhibition, emotional regulation, and shift, predicted social functioning in children with ASD and TD. However, the metacognitive executive processes of initiation, working memory, monitoring, planning, and organization were

predictors of social adaptation only in children with ASD.

Current Knowledge

Understanding the relationships between the aforementioned constructs and the role they play in the socialization deficits of children with ASD may shed light into the nature of these impairments in order to design suitable interventions. Pragmatic comprehension seems to depend on the inference of the speaker’s beliefs, which is the theory of mind (ToM) ability. In fact, some accounts of ASD conceptualize pragmatic language deficits as reflecting a broader impairment in ToM and empathy. A significant correlation has been found in children with autism – but not in a group with developmental delay – between the performance on ToM tasks and the capacity to respond to a conversational partner with new and relevant contingent information (Capps et al. 1998). In another pioneer study by Tager-Flusberg and Sullivan (1995), theory of mind performance was significantly correlated with a number of different narrative measures only for the group with autism. In addition, the individuals with autism gave significantly fewer appropriate explanations for the emotional states of the story characters, which is linked to the capacity to understand other minds. In this regard, the tendency of people with autism to interpret speech literally might suggest that they do not understand the mind of the speaker. Consequently, difficulties in inferring another person’s beliefs may limit the ability to make predictions about his/her behavior, intentions, and feelings, and this affects the ability to communicate and interact socially. But, even successfully completing the ToM tasks, children with autism seem to have more problems with everyday mindreading than younger children with TD. In fact, children and adolescents with HFA can perform advanced ToM tasks as well as their TD peers, and they seem to be able to master the theoretical principles of advanced mental states. However, they may still fail to apply these theoretical principles during everyday social interactions. As Frith et al. (1994) suggested,

some children with HFA learn to resolve explicit ToM problems in experimental contexts in a non-mentalist way. They can use nonsocial strategies that allow them to respond correctly to false belief questions, but they do not generalize the solutions to real life, which also requires the flexible processing of changing emotional and social signals. Therefore, measures of explicit/conceptual ToM competence and measures of applied ToM competence expressed in real world must be considered in research that tries to describe the relationships between the ToM and adaptive social behavior (Hutchins et al. 2016). Results are enhanced when both explicit social cognition performance and implicit social cognition performance in terms of spontaneous perspective taking are included.

Although ToM deficits may contribute to the interpretation of social communication impairments in ASD, many symptoms are not reflections of an underlying deficit in interpreting people from a mentalistic perspective. Indeed, ToM does not appear to be sufficiently highly correlated with broad measures of social functioning to offer a full explanation of this aspect of ASD (Bottema-Beutel et al. 2018). Other factors related to social development, such as executive functioning and its relationship with ToM, should also be considered. Some studies with children with ASD have revealed that EF-planning skills and EF-cognitive shifting significantly contributed to the explained variance of ToM measures (Kimhi et al. 2014). It has also been demonstrated that ToM deficits is associated with EF impairments in ASD, suggesting attipicity in multiple cognitive domains (Pellicano 2007). A possible explanation of this association is that false belief tasks used to assess ToM abilities impose executive demands and, therefore, EF affects ToM expression. Consequently, it is likely that the functioning in one domain be critical for the emergence of the functioning in another area. Specifically, Perner (1998) highlighted that the meta-representative ability underlying ToM must be reached before children self-regulate their behavior. Alternatively, Russell (1996) proposed a causal relation in the opposite direction, suggesting that the abilities to monitor actions and direct our own

behaviors are critical to be able to reflect about our own and others' mental states. In this regard, in a longitudinal study conducted over a 3-year period, early EF and central coherence skills predicted developmental changes in ToM skills, regardless of age, language, and nonverbal intelligence (Pellicano 2010). Accordingly, impaired EF may have a cascading impact in the development of ToM.

Lastly, when considering the relationships between theory of mind, executive functioning, and pragmatic competence and comparing the profile of children with high-functioning autism (HFA) and children with typical development (TD), the results of the group of children with HFA are clearly lower on explicit and applied ToM skills, the main EF indexes, and PC (Berenguer et al. 2018). In addition, it seems that in the relationship between the socialization domain and ToM, EF, and pragmatic competence as mediators, both the ToM skills applied to everyday life and pragmatic competence had a direct and indirect influence on the socialization of children with HFA. This finding suggests the negative impact of deficits in ToM and pragmatic language competence on the social functioning of children with HFA. Similarly, relationships were found between FE (the metacognitive index of the BRIEF) and the socialization abilities of children with HFA, although they did not reach a significant predictive value. However, these findings should be taken as tentative, because the EF-ToM and pragmatic competence relation in autism is complex. It will be important to establish clearly how poor executive abilities affect the development of ToM and how these cognitive processes affect qualitatively the final stages of social cognition development.

Future Directions

Knowledge of underlying factors of social functioning in children with HFA is a priority for designing effective intervention programs. It has especial interest for parents, teachers, and other social agents involved in optimizing the development of children and adolescents with HFA, to

promote evidence-based interventions that minimize isolation and improve social functioning. Particularly, it is useful the evidence that links symptoms of ASD and general social functioning through mediation of pragmatic and ToM abilities, including also aspects of metacognition.

Longitudinal studies will be essential for mapping the developmental trajectories of EF and ToM abilities and for pointing whether EF and pragmatic skills are in fact crucial domains for the later development of ToM in autism and how it affects social behavior. Furthermore, more sophisticated theoretical models of social functioning need to be developed and tested to enhance our understanding of the contributions and interactions between these and other constructs. More research is needed in order to identify profiles of individuals with ASD, for whom different cognitive and developmental mechanisms are in play in regard to social functioning (Bottema-Beutel et al. 2018).

Moreover, it would be necessary to go beyond techniques based on applied behavior analysis to adopt multicomponent programs that take different aspects into account. This approach appears to encourage social perception and problem-solving capabilities, promoting a more advanced ability to define and recognize emotions in social situations. Specifically, it has proved to be effective in enhancing the capabilities for group peer interaction and for improving awareness of others and social cognition among children with HFA. The implementation of a school-based, teacher-facilitated social skills intervention known as Program for the Education and Enrichment of Relational Skills (PEERS) has also shown significant improvements in responsiveness and social cognition in children with autism (Laugeson et al. 2014). The participants demonstrated overall improvement in social responsiveness, particularly in the areas of social motivation, social awareness, social communication, and decreased autistic mannerisms. The results of PEERS on the importance of active participation of the child and teachers as significant mediators of the program effect are in line with the conclusion of a recent meta-analyses underlining the valuable role of the

parents in pragmatic language interventions (Parsons et al. 2017).

In addition to considering the natural contexts in the interventions of children with autism, it should not be forgotten that the association with positive emotional experiences may be able to promote spontaneous orientation toward social communication, increase socialization opportunities, and facilitate the learning and practice of mentalist and pragmatic skills.

Son-Rise Program

Robert H. LaRue
Douglass Developmental Disabilities Center,
Rutgers, The State University of New Jersey, New
Brunswick, NJ, USA

Synonyms

[Options method](#)

Definition

The Son-Rise Program was first described by Kaufman in the 1970s as a treatment for children with autism whereby the parent or therapist increases child motivation for social interaction

by “joining in” or imitating child-led behavior. Kaufman based his therapy on the approach he developed to treat his young son with autism – an approach that Kaufman described as successful. The intensive one-to-one therapy is conducted in a distraction-free playroom, and the parent or therapist follows the child’s lead by imitating the child’s repetitive behavior and routines, or “isms.” This showing of acceptance of the child’s behavior is thought to increase the child’s motivation to interact with others so that the therapist can build on the shared activity by encouraging social interaction and communication. The Son-Rise Program is implemented by parents and volunteer therapists in the home environment; parents coordinate and supervise the program following training through the Options Institute. No formal research has been conducted to assess the effectiveness of the Son-Rise Program. In addition to treating individuals with autism, the Son-Rise Program has been used to treat children and adults with other developmental disabilities such as Down syndrome.

Sotos Syndrome and ASD

Chloe Lane and Megan Freeth
Department of Psychology, University of
Sheffield, Sheffield, UK

[Cerebral gigantism](#)

Short Description or Definition

Sotos syndrome is a congenital overgrowth disorder caused by haploinsufficiency of the NSD1 gene. The cardinal features of the syndrome are overgrowth (defined as height and/or head circumference > 97th percentile) with advanced bone age, macrocephaly, characteristic facial appearance, and intellectual disability. Although these features are consistent within the Sotos syndrome population, the severity of the phenotype is variable. The majority of individuals with Sotos syndrome have mild-moderate intellectual disability or borderline intellectual functioning. In addition, increased likelihood of autism spectrum disorder (ASD), attention deficit hyperactivity disorder (ADHD), anxiety and aggression/tantrums have been reported in individuals with Sotos syndrome.

Categorization

The identification of a genetic abnormality responsible for Sotos syndrome was first established in a Japanese sample (Kurotaki et al. 2002). The authors identified that Sotos syndrome is caused by haploinsufficiency of the NSD1 (nuclear receptor binding SET domain protein 1) gene. The NSD1 gene encodes SET domain-containing histone methyltransferases and is located at chromosome 5q35 (Tatton-Brown and Rahman 2013). Sotos syndrome is caused by intragenic mutations of the NSD1 gene or 5q35 microdeletions encompassing NSD1 and these abnormalities result in loss of function. Subsequent research investigated the prevalence of NSD1 abnormalities in a sample of 266 individuals with a clinical diagnosis of Sotos syndrome. The findings from this study identified that abnormalities of the NSD1 gene were present in more than 90% of individuals with a clinical diagnosis of Sotos syndrome (Tatton-Brown et al. 2005).

As well as having macrocephaly, individuals with Sotos syndrome typically display distinctive neurological abnormalities. Schaefer et al. (1997) investigated structural brain abnormalities in 40 participants with Sotos syndrome, using magnetic resonance imaging (MRI). The findings

indicated that participants displayed a characteristic pattern of abnormalities. Specifically, participants displayed abnormality of the corpus callosum, ventricular abnormalities, midline abnormalities, and delayed or disturbed maturation of the brain.

Epidemiology

The estimated incidence of Sotos syndrome is approximately 1 in 14,000 live births (Tatton-Brown and Rahman 2004). In the majority of cases, the NSD1 abnormalities which cause Sotos syndrome are *de novo*, meaning that they occur spontaneously (Kurotaki et al. 2002). However, the syndrome has an autosomal dominant inheritance pattern, meaning that a child of an individual with Sotos syndrome has a 50% chance of also having the syndrome. A small number of familial cases arising from autosomal dominant transmission have been reported in the literature (Tatton-Brown et al. 2005; Tatton-Brown and Rahman 2007). The syndrome is one of several single-gene disorders associated with overgrowth and intellectual disability and has recently been identified as by far the most prevalent of this category of disorder (Tatton-Brown et al. 2017).

Natural History, Prognostic Factors, Outcomes

Sotos syndrome was initially identified by Sotos et al. (1964) who observed five patients with similar clinical features: excessively rapid growth, acromegalic features, and a nonprogressive cerebral disorder with mental retardation. This combination of features was considered to be attributable to a specific syndrome which was termed “Sotos syndrome.” Subsequent research has confirmed these cardinal features (overgrowth, macrocephaly, characteristic facial appearance, and intellectual disability) in larger samples of individuals with Sotos syndrome (Cole and Hughes 1994; Tatton-Brown et al. 2005). As Sotos syndrome is associated with macrocephaly, initial research often used the terms “cerebral gigantism” and “Sotos syndrome” interchangeably

to refer to the same condition but “cerebral gigantism” is no longer used to describe individuals with Sotos syndrome.

Overgrowth (defined as height and/or head circumference > 97th percentile) is an easily identifiable feature as children with Sotos syndrome are large for their age and tend to be considerably taller than their peers. However, increased height usually becomes less apparent after puberty and in many cases, adults with Sotos syndrome are not significantly taller than those in the general population (Tatton-Brown and Rahman 2007). In contrast, macrocephaly is a stable feature of the syndrome and usually persists throughout adulthood (Tatton-Brown and Rahman 2007). The facial appearance is characterized by a prominent forehead, high anterior hairline, prominent chin, and downslanting palpebral fissures (Dodge et al. 1983). The characteristic facial appearance is most recognizable between the ages of 1 and 6 years, and the facial features often become less apparent in adulthood (Tatton-Brown and Rahman 2007). As the clinical features tend to be more prominent and recognizable in childhood, it is important for individuals displaying this combination of features to be referred for evaluation as early as possible.

A number of medical issues are associated with Sotos syndrome. Approximately 70% of infants with Sotos syndrome develop neonatal jaundice and/or have difficulty with feeding. In addition, cardiac and renal anomalies, seizures, and scoliosis occur in 15–30% of individuals with Sotos syndrome but the type and severity of these issues is variable (Tatton-Brown and Rahman 2007).

To date, most of the published literature reporting data on cognition and behavior in Sotos syndrome has focused on children with the syndrome, and therefore, there is limited understanding of outcomes in adulthood for individuals with Sotos syndrome (Lane et al. 2016). However, research investigating cognition in a sample of 52 adults and children with Sotos syndrome indicated that intellectual disability persists throughout adulthood and that the cognitive profile is

consistent in both adults and children with Sotos syndrome (Lane et al. [under review](#)).

Clinical Expression and Pathophysiology of Sotos Syndrome

Intellectual disability is one of the cardinal features of Sotos syndrome and the majority of individuals have mild-moderate intellectual disability or are in the borderline range (Lane et al. 2016). However, significant variability in intellectual functioning has been reported within the literature, ranging from severe intellectual disability to average intellectual ability. Broadly, the syndrome is associated with relative strength in verbal IQ and relative weakness in performance IQ (Lane et al. 2016). Research investigating the cognitive profile in more detail has identified that individuals with Sotos syndrome display a clear and consistent profile of relative cognitive strengths and weaknesses. Specifically, the Sotos syndrome cognitive profile is characterized by relative strength in verbal ability and visuospatial memory but relative weakness in nonverbal reasoning ability and quantitative reasoning (Lane et al. [under review](#)). Although language and communication delays have been reported in several studies, in general, language abilities have been found to be consistent with overall level of intellectual functioning (Finegan et al. 1994). Fine and gross motor skills are often delayed in childhood and this can be attributable to the large size of the child, as well as the associated hypotonia and poor coordination which are common in children with Sotos syndrome (Tatton-Brown and Rahman 2007).

In terms of the behavioral phenotype, ASD is the most researched behavioral issue within the Sotos syndrome population. Social communication impairment and difficulties with restricted interests and repetitive behaviors have been reported in 68% (Sheth et al. 2015) and 83% (Lane et al. 2017) of individuals with Sotos syndrome. Other behavioral issues such as ADHD, anxiety, and aggression/tantrums have been

reported in the literature, but to date, these behaviors have not been systematically investigated in large samples of individuals with Sotos syndrome so the prevalence of these behaviors is unknown (Lane et al. 2016). As children with Sotos syndrome are often large for their age, they may be mistaken as older and more able than their actual developmental level and this assumption may result in frustration and temper outbursts (Cole and Hughes 1994). This may account for the aggression/tantrums that have been reported in the literature.

Evaluation and Differential Diagnosis

Until the identification of the genetic abnormality associated with Sotos syndrome was identified in 2002 (Kurotaki et al. 2002), the syndrome was diagnosed on the basis of clinical features. However, genetic screening is now widely available. Therefore, individuals who meet the clinical criteria and are suspected of having Sotos syndrome can be screened to check for abnormality of the NSD1 gene.

Other examples of single-gene disorders associated with overgrowth and intellectual disability include Weaver syndrome (Weaver et al. 1974) and Tatton-Brown Rahman syndrome (Tatton-Brown et al. 2014). As these syndromes are also associated with overgrowth and intellectual disability, there is some overlap in the phenotypes of these syndromes. However, each of these disorders is caused by a distinct genetic abnormality and therefore molecular testing is crucial for differentiating between these overgrowth syndromes and for ascertaining the accurate diagnosis for an individual.

Research has identified that the majority of individuals with Sotos syndrome display clinically significant behavioral symptomatology associated with ASD (Lane et al. 2017). In addition, the severity of ASD symptomatology does not differ between males and females with Sotos syndrome. However, severity of ASD symptomatology has been found to be affected by age, with

less severe behaviors observed in young children (2.5–5 years) and adults (20+ years), when compared to children (5–19 years) with Sotos syndrome (Lane et al. 2017). This indicates that ASD symptomatology may be more apparent in children with Sotos syndrome and that severity of ASD symptomatology may decrease in adulthood. Therefore, individuals with a diagnosis of Sotos syndrome who experience social communication impairment and difficulties with repetitive behaviors may require a comprehensive assessment for ASD. A comorbid diagnosis of ASD may be warranted for some individuals with Sotos syndrome.

Treatment

Sotos syndrome is a congenital disorder and is therefore a lifelong condition, which does not require treatment. Within the Sotos syndrome population, there is significant variability in the severity of the phenotype. It is therefore important to consider the needs of the individual when considering appropriate support and issues should be treated symptomatically. To date, syndrome-specific support and interventions have not been established for individuals with Sotos syndrome.

Within the Sotos syndrome population, individuals should be monitored for medical issues such as cardiac and genitourinary anomalies, neonatal jaundice, neonatal hypotonia, seizures and scoliosis, which are common in Sotos syndrome (Tatton-Brown and Rahman 2004) and appropriate treatment should be provided for these issues if they arise. For example, children may develop scoliosis and require a back brace or in some cases, surgery. In addition, seizures are common and some individuals may need to take medication to control the seizures (Tatton-Brown and Rahman 2004).

A cognitive assessment may be useful to ascertain the intellectual ability of a child with Sotos syndrome and to consider the appropriate educational setting for the child. Approximately 50% of children with Sotos syndrome attend special

educational needs schools, while the remaining 50% attend mainstream schools but often require additional support. As children with Sotos syndrome have developmental delay, speech and language therapy may be useful in early childhood to support language development. Similarly, children with Sotos syndrome often have fine and gross motor delays so occupational therapy might be appropriate in early childhood. As the phenotype of Sotos syndrome has not yet been clearly defined, a comprehensive assessment of each individual with Sotos syndrome will inform effective and appropriate strategies and support which can be targeted to the needs of the individual.

Introduction

In this entry, an attempt is made to provide an overview of autism spectrum disorders (ASD) in South Africa. To this end, attention will be drawn to the historical context, current treatment options, legal mandates for service, research efforts, and relevant controversies. Compiling such a description presents a methodologically complex task – very little systematic data are available about ASD in South Africa, at least in part attributable to the absence of centralized bodies tasked with the monitoring of available services. There are even less data available in peer-reviewed journals, in line with the findings of Tomlinson and Swartz (2003), who demonstrate that in a survey of 764 journal articles related to ASD, only 4 % were outside the USA or Europe. A systematic review of “autism” and “Africa” in the Web of Science over the 10-year period of 2002–2012 revealed 33 papers about or from Africa, in rather stark contrast to >18,000 peer-reviewed papers on autism over the same period in the rest of the world (personal communication, Prof P J de Vries). This entry therefore represents a careful balance between relying on robust data sources and providing sufficient detail such that a helpful picture can be drawn. Our data sources therefore include websites of specific organizations,

estimates of service delivery based on available databases, and perspectives of key role players – including managers of NGOs, clinicians in public and private practice, and academic psychiatrists. Every effort has made to be as transparent as possible in describing data sources, and when no citation is presented, the perspective can be assumed to be the product of the accumulated experience of the authors.

Historical Background

As it is for much of sub-Saharan Africa, the history of autism in South Africa is brief and poorly documented. A survey of six African countries conducted in 1978 by Viktor Lotter (1978), a pediatrician working in the UK at the time, was probably the first systematic study to show that there were children in Africa (Ghana, Nigeria, Kenya, Zimbabwe, Zambia, and South Africa) who displayed patterns of behavior consistent with the construct of autism as understood at the time. Lotter was particularly interested in looking for autism in “indigenous African children,” defined by him as “black African children raised by black African parents.” He therefore took great care to exclude so-called mixed race or non-African black children. He also compared his African sample to a group of children from Middlesex in London identified with autism. Out of 1300 African children with intellectual disability, he identified 30 with autism-related behaviors; nine children met the “western criteria” for autism of the time. Interestingly, he found verbal and nonverbal children with autism and rates of epilepsy, gender ratios, and social backgrounds to be relatively similar to those of his Middlesex sample. On direct comparison of the African and Middlesex samples, he described differences in specific autistic characteristics. For instance, he found no flapping, ritualistic play, or self-injury in the African sample, but did report an overrepresentation of “other marked movements” and “carrying, banging, or twisting of objects.” He argued that there may be less autism in Africa

and that some of the phenomena typically associated with autism may be uncommon in African settings (Lotter 1978).

Subsequent studies have confirmed that autism has similar gender ratios in Africa as the rest of the world (Ametepee and Chitiyo 2009), and at least one subsequent study has highlighted the comparative rarity of certain movements (like rocking) that occur more commonly in western populations (Mankoski et al. 2006). Additionally, it has been noted that as in Kanner's original description of children with autism, published cases in Africa tend to be of children from higher socioeconomic backgrounds (Ametepee and Chitiyo 2009; Kanner 1943). The most likely explanation is that wealthier individuals live in closer proximity to medical centers and are therefore more likely to be able to access services. This finding of SES as a correlate for access to services maps well onto similar observations in the USA (Durkin et al. 2010). It has now become accepted that autism occurs across Africa. To date there have been no systematic investigations into the prevalence of autism in Africa. There may be many potential reasons for this lack of epidemiological data on autism in Africa, including the fact that communicable diseases have dominated health priorities in Africa over the last century, combined with the lack of systematic research programs in autism over the last number of decades, and the lack of appropriate screening and diagnostic tools for autism in African languages (Grinker et al. 2012).

In response to a growing recognition of the existence of autism, combined with very limited available services, the nongovernmental organization (NGO) Autism South Africa was founded in 1989 (Autism South Africa 2014). The history of autism in South Africa has been influenced in a significant way by the growth and the development of this organization. The group initially consisted of concerned parents and professionals that were primarily engaged in lobbying government, but, given increasing requests for the provision of support and assistance to families, the group expanded in scope and established permanent, full-time offices in 1997. Today, Autism South Africa serves as a resource for parents and families, providing regular parent training and

facilitating referral of both families and individuals with autism to relevant educational and supportive resources. Autism South Africa has branches and staff in a number of South African Provinces. There are also other ASD NGOs, including Autism Western Cape, based in Cape Town, and Action in Autism, based in KwaZulu-Natal. Despite the growth of organizations like Autism South Africa and other NGOs, there continues to be a significant shortage in services for both family members and individuals with autism, with an estimated 135,000 individuals with ASD in South Africa not receiving appropriate services (Bateman 2013).

Legal Issues: Mandates for Service

There are currently no legal mandates for ASD-specific services in South Africa. Although the South African constitution is internationally renowned for enshrining equal rights for all, significant resource shortages prevent implementation of this ideal. For example, although all children in South Africa have a right to education, with only five government-funded schools tailored to ASD individuals, many children are left underserved. As a member of the WHO, South Africa adopted the resolution on autism spectrum disorders (World Health Organization 2013) (http://www.who.int/mental_health/action_plan_2013/eb_resolution_childhood/en/), which urges member states to expand capacity for services, develop and implement policies, promote research and awareness, and provide focus on community-based (rather than long-term institutional) treatment along with several other goals. The resolution is focused on an implementation period from 2013 to 2020. To date there are no published reports of progress currently available for South Africa.

Overview of Current Treatments and Centers

The South African healthcare system is for the most part sharply divided between a well-resourced private sector, serving around 20 % of

the population, and a relatively resource-limited state sector, which serves the remaining 80 %. However, even in the private sector, services for ASD are of variable quality, being for the most part unmonitored and not always employing evidence-based practices. In addition to being non-standardized, current services are remarkable for being of greatly insufficient capacity. Representatives from the University of Cape Town's Autism Research Group note that ASD-specific schools in South Africa have several year waiting lists, often leading to children being accepted to these facilities and receiving appropriate intervention 3 or 4 years after the time of diagnosis (UCT Department of Psychology Autism Research 2014). These children are nevertheless more fortunate than a majority who are unable to receive specialized education altogether (Bateman 2013). Available schools, diagnostic centers, and residential treatment facilities are discussed below.

Schools

There are only nine schools specifically set up for individuals with ASD in South Africa (Autism South Africa 2014). Four of these are private schools that offer very comprehensive programs, including pre- and after-school care, holiday programs, and access to a wide range of recreational facilities. The remaining five are state funded, often with support from NGOs. The first government school for children with ASD was the Vera School, in Cape Town, founded in 1970. It is regarded as a specialist resource center in the management of autism spectrum disorder. The school has 145 pupils and can accommodate 35 on site in hostels. It has 74 members of staff and is publicly funded through the Western Cape Education Department (Charity SA 2014).

The Alpha School was established in 1974 by what was then known as the Society for the Autistic Children. It was originally set up in a living room of a private home in Athlone, Cape Town, and after various relocations, it moved to its current premises in Woodstock, Cape Town, in 1995. It has traditionally served the less privileged sectors of the Western Cape population. At present it has approximately 76 learners up to the age of 17, in ten classrooms with a variety of volunteers and students assisting in the activities of the

teachers and supplementary staff – which includes speech therapy, occupational therapy, and psychology. The children are occupied with classwork, swimming, and various other activities including a peace garden, which is an initiative that involves the community and the children taking ownership in cultivating a patch of a vegetable garden (Scanza 2014).

As an example in the private sector, “The DreamTree School” in the relatively wealthy Western Cape Province of South Africa is a well-resourced center with occupational and speech therapists, experienced special education teachers, and psychologists on site (The Dream Tree School 2014). This facility cites evidenced-based practices such as applied behavioral analysis (ABA) and social skills training as a basis for their approach. Although there are fewer schools in other provinces, one exemplar in the non-private sector is the UNICA School in Menlo Park, Gauteng. This facility is operated as a public benefit organization (PBO), in partnership with the government, donors, and nominal fees payable by the parents of attendees (around \$1000 per year in 2014 for tuition). The UNICA School attracts students from across South Africa, Swaziland, and neighboring countries and cites the TEACCH curriculum as being central to their approach (The Unica School for Autism 2014).

Six of the ASD-specific schools are in the Western Cape Province of South Africa, with the other three in the Gauteng and Eastern Cape provinces. Given the small number of schools in the context of a population of 52 million people, clearly many children with ASD are unable to attend these facilities. Other sources of education include special programming within regular schools and attendance of schools that target children with special educational needs in a much broader sense. Unfortunately, there are no systematic data on the quality and suitability of the education obtained by ASD individuals at these organizations, and it is assumed to be highly variable across different regions.

While the existing educational programs listed above often refer to ABA, TEACCH, Makaton, and PECS, it is unclear whether more contemporary, relationship-based intervention approaches

such as the Early Start Denver Model, JASPER, Pivotal Response Training, etc., are utilized in schools. It is also worth bearing in mind that the statutory school-going age is 7 years and that no governmental preschools exist. No child with autism under the age of 6 or 7 will therefore have access to public sector early intervention or educational programs.

Assessment and Diagnosis

It is assumed that university hospitals in South Africa provide diagnostic services for individuals with symptoms suggestive of ASD. However, with only eight medical schools in South Africa, the capacity is insufficient to ensure that a majority of individuals receive an early diagnosis. There are only nine qualified neurodevelopmental pediatricians in South Africa, with a national training capacity of two candidates per year, and only around 46 specialist child and adolescent psychiatrists in South Africa (de Vries et al. 2013; Skosana 2014). In the Western Cape, which is a home to three relatively large centers (Tygerberg Hospital, Lentegour Hospital, Red Cross Children's Hospital), around ten individuals are evaluated for ASD per week. In addition, the organization Autism South Africa runs an assessment clinic once a month in Johannesburg, targeting individuals who do not have access to academic medical centers.

The availability of accurate diagnostic services within the private sector is unclear. There are a very small number of appropriately experienced pediatricians and child and adolescent psychiatrists in South Africa, and anecdotal evidence suggests that general practitioners (who form a significant majority of overall providers) are often uncomfortable with diagnosing neurodevelopmental disabilities (Bateman 2013).

Residential Treatment

Available residential treatment is provided by NGOs and includes the Horizon Farm in the province of KwaZulu-Natal (Horizon Farm Trust 2014) and Lethabo Le Khutso Adult Care center in Pretoria, Gauteng province (Association For

Autism 2014). The Horizon Farm is operated by the Horizon Farm trust, has been in operation since 1994, and is situated on a 30-acre farm, facilitating an outdoor lifestyle for 30 individuals with intellectual disabilities, including but not limited to ASD. This facility reports an ever-increasing waiting list. The Lethabo Le Khutso Adult Care center is a facility that provides residential care for adults with ASD and is an initiative of the Association For Autism, an NGO. In most parts of South Africa, there appear to be no residential treatment facilities available specifically set up for adults with autism with/without intellectual disability.

Other Services

The bulk of additional supports and services are provided by NGOs. These include day programs, like the CARE Day School in Johannesburg, Gauteng province (Centre For Autism Research and Education 2014), and the Star Academy with locations in Gauteng and KwaZulu-Natal (The Star Academy 2014). These organizations provide a range of services with a prominent focus on applied behavioral analysis. The organization Autism South Africa, highlighted previously, acts broadly in providing screening clinics and helping parents get connected with available treatment while serving as advocates for the ASD community at the governmental level (Autism South Africa 2014). The Els for Autism Foundation was founded in 2009 by the well-known South African golfer Ernie Els and his wife Liezl, who have a son affected with ASD (Ernie Els Foundation 2014). The goal of this NGO is to support an e-learning platform that provides access to ASD education and therapy, as well as online training at no cost. These and other similar organizations are a significant part of the ASD treatment landscape in South Africa.

Overview of Research Directions

Prior to 2012, there was no systematic research programs on autism anywhere in Africa,

including in South Africa. In 2012 Prof Petrus de Vries founded the Center for Autism Research in Africa at the University of Cape Town. The goals of this initiative are to develop an interdisciplinary center for ASD and related disabilities across themes of awareness, training, clinical work, and research (Malcolm-Smith et al. 2013). Current programs within the center include:

1. The translation and validation of screening tools for ASD such as the social communication questionnaire (SCQ) and modified checklist for autism in toddlers (M-CHAT) into Afrikaans, isiXhosa, and Kiswahili. In addition to validation of psychometric properties, efforts are being made to ensure that these measures are culturally appropriate using mixed-method research approaches.
2. The translation and validation of diagnostic tools like the Autism Diagnostic Observation Schedule (ADOS) and Autism Diagnostic Interview-Revised (ADI-R) into Afrikaans, isiXhosa, and Kiswahili.
3. Development of post-diagnostic programs, including programs for psychoeducation and parent training. Tied to the development of these programs is the evaluation of existing programs developed in the UK, with assessment of their suitability for the South African context.
4. Identification of evidence-based interventions and, in particular, parent-/caregiver-led interventions, which are particularly salient given resource limitations and the limited number of expert therapists available.
5. The training of staff in primary, secondary, and tertiary level care centers in early detection, diagnosis, and treatment of ASD.
6. Evaluation and development of service models. Given the limited existing services, even in better-resourced parts of South Africa, evaluation of existing educational services (including needs and gap analysis) is crucial for the development of sustainable, integrated services for individuals with ASD and their families.
7. Investigating the potential for use of technology in low-resource environments to facilitate the abovementioned aims and improve early detection, diagnosis, and treatment.

This group therefore has an ambitious research agenda, which is likely to be highly impactful in improving understanding of ASD in South Africa. However broader involvement from multidisciplinary clinical and academic colleagues across all academic medical centers remains an important need.

Cultural Factors and Controversies

There is a significant lack of awareness surrounding ASD, particularly in rural areas of South Africa (Autism South Africa 2014). This, in combination with the dearth of available evidence-based treatments for autism, has maintained widespread misconceptions about the nature of the disorder, as well as propagation of pseudoscientific diagnostic and treatment practices. In certain communities, ASD continues to be viewed as evidence of demonic possession, or a sign of punishment from the individuals' ancestors (Autism South Africa 2014). As reported by Grinker et al. (2012), parents of children with ASD in rural communities reported taking their children to traditional healers for consultations about treatment. However, it is of interest that these parents also reported the utility of having the "western" diagnosis of ASD provided to their children, as it reduced their concerns about a potential spiritual cause for the child's difficulties. This study also noted an interesting fact about child-care centers or crèches operating in these communities. Staff working at crèches reported the expectation that after the age of 2, direct eye contact with elders would be discouraged and potentially seen as disrespectful – an interesting finding suggesting the possibility of differential cultural expectations regarding certain social communication behaviors that are used as red flags for autism.

In wealthier, urban areas, a different set of challenges exist, with a number of expensive, private practices offering nonevidenced-based explanations and treatments for individuals with ASD. These practices are run by individuals with a broad range of qualifications and most often offer treatments centered on viewing autism as a consequence of gastrointestinal dysfunction. These interventions may include restrictive diets, herbal medications, homeopathic remedies, and supplementation. Many practitioners operating in this paradigm report their alignment with the now-defunct Defeat Autism Now! Program. The surprising prominence of such practitioners is likely a consequence of the limited availability of adequately trained child and adolescent psychiatrists and neurodevelopmental pediatricians in South Africa.

Spain and Autism

José Luis Cuesta Gómez

Faculty of Education, Universidad de Burgos,
Burgos, Spain

Historical Background

Much of the data that allows us to reconstruct the history and the current situation of autism in Spain has been taken from the compilation prepared by Adam Feinstein, principally through Mercedes Belinchón, Doctor in Psychology and professor of the Autonomous University of Madrid, who has played an important role in that institution and promoted different initiatives in relation with education and research of special importance (Feinstein 2016).

The support services specifically for people with ASD (autism spectrum disorder) that began to emerge in Spain were promoted by professionals, principally with links to the health services, many holding a clear psychodynamic orientation that characterized their early training. The most important references in those first phases are the Centro TAURE (Madrid) that opened in 1973 and the Centro Carrilet (Barcelona), founded in 1974. In these first years of life, the professional life of Doctor Ángel Díez Cuervo (Neuro-pediatrics) may be highlighted. He has been a leading light in Spain, supporting the launch and the growth of institutions. His important contributions have added to our knowledge of scientific evidence-based practices and their development.

This first phase in the development of specific support services extended up until the mid-1970s, a time at which a family-centered model began to gain in popularity, through associations that characterize the reality in which we now live. They have managed to generate the majority of resources specific to our country. In 1976, two of the associations were launched that supported the successive formation of other organizations of parents of people living with autism; APNA

(Madrid) and La Garriga (Barcelona), managed by Isabel Bayonas and Joan Roca, respectively, which have for decades contributed to the development of policies of support for the collective and the launch of associations in other geographical areas of the country.

Before the end of the 1970s, other entities were set up that continue to be nationwide references to this day, such as the Asociación Guipuzcoana de Autismo (Gautena). It enjoys the technical support of the child psychiatrist Joaquín Fuentes Biggi, a reference for autism both within and outside Spain. In 1979, the Association New Horizons (Madrid) was born, one of the first entities that has developed services for adults with ASD in Spain.

The establishment of these organizations went on to generate cooperative alliances between families and professionals, which were shaping a model of services where education came to be seen as the best development tool for people with ASD. The psychodynamic perspective has gradually lost ground at centers and support services, except in Cataluña, a regional community where it is still very popular. The mothers and fathers who pioneered it, together with professionals such as Ángel Díez Cuervo and Ángel Rivière Gómez, contributed the philosophical and conceptual groundwork that still serves as a reference today for many associations and has assisted them in their development throughout Spain. Their contributions reinforced the biological factor as the origin of autism, burying the myths that blamed the families, and the value of integral education as a better tool with which to promote the development for people with ASD.

It had special importance at the I International Symposium on Autism, organized in Madrid in 1978, by APNA and SEREM (*Servicio de Recuperación y Rehabilitación de Minusválidos Físicos y Psíquicos*) [Recovery and Rehabilitation Service for the Physically and Mentally Disabled] under the catchphrase “Help me to know who I am.” This meeting, directed at professionals, families, public authorities, and society in general, had many repercussions throughout Spanish territory. As from that point, people began to

hear of a different approach to autism, unlike the erroneous theories and interpretations that had up until the present been prevalent. This initiative was crucial, as it placed the different models that coexisted at that time in our country on the table: psychodynamic, behaviorist, and the perspective that defined the biological origin of autism and interventions from the cognitive behavioral point of view through educational processes of intervention. In that symposium, the families reaffirmed the need and the responsibility to play an active role in setting up services and demands for support. Another of the important consequences of the Symposium was the launch on 4 May 1978 of a Committee composed of families of nine different nationalities (Australia, France, Germany, Holland, Ireland, Norway, Portugal, Spain, and Sweden), for the organization of the International Coordinating Office for Parents of Autistic Children and Adults, with the objective of lobbying for people with autism and recognition that each autistic person needs education, treatment, and specialized and individualized care; has the right to develop his or her potential to a maximum as human beings; and to have a decent place in society (Martínez et al. 2010).

Moreover, in the field of the associations, one initiative that has profoundly affected the development of autism in Spain has been the birth of the AETAPI, now the *Asociación Española de Profesionales del Autismo* [Spanish Association of Autism Professionals], driven by the professionals themselves as a space of exchange, development, and education. This organization has contributed to generating a consensual model of intervention, based on good practice with scientific evidence, and at present supports professionals, people living with ASD, families, and organizations in the defense of rights and a strategy to confront unscientific practices that are still sold today as “miracles.” Every 2 years, AETAPI organizes a congress on autism and promotes the development of good practice and research, through the Angel Rivière Prizes. This organization has over the years counted on the support of professionals such as Javier Tamarit, who began his links with autism through his work at CEPRI, at the end of the 1970s,

and contributed in a very significant way to the development of knowledge on ASD in Spain.

Over time, associations have been extending across national territory and have been grouping themselves together in federations, in different autonomous communities and, at a national level, in confederations. The FESPAU Confederation, born in 1994, at present represents 25 organizations, and the Spanish Autism Confederation, born in the same year, groups together 77 entities comprising families, people with ASD, and professional linked to the collective. In 2004, the Asperger Spain Federation was launched. At present, the three organizations jointly collaborate on some initiatives, especially those oriented towards the promotion of state policies for assistance to people with ASD.

In 2001, the *Grupo de Estudios de los Trastornos del Espectro del Autismo* (GETEA) [Study Group on Autism Spectrum disorders] was formed, as a part of CISAT (*Centro de Investigación sobre el Síndrome del Aceite Tóxico*) [Research Center on the Toxic Oil Syndrome], the forerunner to the present-day *Instituto de Salud Carlos III* [Institute of Health Carlos III] with the objective of conducting a project to gain greater knowledge of the reality of autism in Spain and to recommend ways of improving assistance, training, and research into ASD. This group knew how to harness the necessary interest, knowledge, and experience to confront the present-day challenges of research and practice related with autism, consisting in the study of the causes of the increased prevalence and etiology of these disorders, as well as the aspects related with the detection, diagnosis, and intervention directed at people who present it. As a result of the work of this group, four guides of good practice were published for the early detection, diagnosis, treatment, and investigation of autism spectrum disorders in the *Revista Española de Neurología* [Spanish Journal of Neurology].

At present, the IIER continues to be involved in the development of ASD-related projects in both the state sector and the European context and collaborates at an international level in epidemiological research into these types of disorders.

Legal Issues, Mandates for Service

This historic moment coincided with the transition to democracy in Spain, which was accompanied by greater involvement and initiative in civil society to transform reality, generating a significant movement of associations in the 1970s and 1980s. Moreover, legislation and initiatives were advanced that favored the recognition of the rights of people with disability and their inclusion in education, society, and the workplace, as well as the consolidation of entities responsible for the development of actions directed at these collectives, among the most important of which are the following:

Ley General de Educación [General Law on Education] of 1970 that recognizes the right to education of people with autism, adopting the term Special education and recognizing it as a specific modality.

Decreto de 23 de mayo de 1975 [Decree of 23 May, 1975], establishing the Instituto Nacional de Educación Especial (INEE) [National Institute of Special Education] as an autonomous organism, dependent on the Ministry of Education and Science, which will be a key piece in the progress and the development of attention to students with special educational needs through specialized centers.

Approval of the Royal Board of Special Education in *Real Decreto de abril de 1976* [Royal Decree of April 1976], chaired by H.M. Queen Sophia, the forerunner of the present-day Real Patronato sobre Discapacidad [Royal Board on Disability]. In addition to the Ministry of Education and Science, the Ministries of the Treasury, Territorial Government (now defunct), Justice, Employment, and Social Security all formed part of it, as well as other personalities of recognized prestige, appointed by H.M. Queen Sophia.

The Spanish Constitution (1978) dedicated its article 49 to recognizing the rights of the collective of people with disability, mentioning that the public authorities will uphold a policy

of prevention, treatment, rehabilitation, and integration, and will ensure the delivery of the specialized attention that they require and will give them special help for full enjoyment of the rights that this provision grants to all of its citizens.

The *Ley de Integración Social de los Minusválidos, de 7 de abril de 1982* (LISMI) [Law of Social Integration of the Disabled, of 7 April 1982] is a norm of special importance in Spain, because it explicitly regulates the right of disabled people to inclusion in social, educational, and employment activities. In the area of education, under the third article of Title VI, their inclusion in the ordinary system of general education is contemplated, receiving in each case the support and the resources that the law envisages.

The *Real Decreto del 6 de marzo de 1985* [Royal Decree of 6 March 1985] regulates Special Education in a specific way as an option that forms part of the national educational system, contemplating the inclusion in ordinary centers with the support that each person requires, and where serious difficulties exist, schooling will take place in specific units or centers.

The *Real Decreto 2377/1985, por el que se aprueba el Reglamento de Normas Básicas sobre conciertos educativos* [Royal Decree 2377/1985, in approval of the Rule of Basic Norms on educational agreements], supported the creation of many of the specific educational centers, the majority promoted and managed by families, and subsidized with public funds.

The consolidation of educational integration came in 1990, with the *Ley de Ordenación General del Sistema Educativo* [Law on the General Organization of the Educational System], which incorporates the terms of pupils with special educational needs and determines that they will have access to the necessary supporting resources and the curricular adaptations that they may require.

Ley 39/2006, de 14 de diciembre, de Promoción de la Autonomía Personal y Atención a las personas en situación de dependencia [Law 39/2006, of 14 December, on the Promotion of Personal Independence and Attention to

people in a situation of dependency], which regulated the universal right to different modalities of services and their delivery to people living with disabilities. On that basis, the professional figure of the Personal Assistant was defined as personalized support in the fields and times at which the disabled person may most require so.

On 13 December 2006, the Convention on the Rights of Persons with Disability was adopted in New York and its Optional Protocols, international legal instruments that were ratified by Spain and entered into force on 3 May 2008, having since then formed part of our legal order.

Real Decreto Legislativo 1/2013, de 29 de noviembre, por el que se aprueba el Texto Refundido de la Ley General de Derechos de las Personas con Discapacidad y de su Inclusión Social [Royal Legislative Decree 1/2013, of 29 November, in approval of the Consolidated Text of the General Law of the Rights of People with Disabilities]. This regulation was based on the proposal in the Convention of the Rights of People with Disability (ONU 2006).

In 2013, the rights of people with disability advanced in Spain, with the recognition, among others, of the right to full participation and inclusion, initiated at the earliest possible stage through the enactment of the *Ley General de Derechos de las Personas con Discapacidad y de su Inclusión Social* [General Law of the Rights of Persons with Disability and of their Social Inclusion] published in the BOE of 3 December 2013. Its drafting was based on the proposal advanced at the International Convention of the Rights of Persons with Disability, approved at the United Nations General Assembly in 2006 (UNO 2006). Article 26 of that Convention specifically refers to the right to education in the context of “full inclusion and participation in all aspects of life.” Both initiatives are based on the principle of nondiscrimination towards persons with disability, and they understand education as part of comprehensive habilitation and rehabilitation services. It is stressed that education should start at the

earliest possible stage and should be based on a “multidisciplinary assessment” of the “individual needs and strengths” of the person with disability, as well as opportunities in their own community. Appropriate habilitation and rehabilitation services and support will be oriented towards decision-making and measures to attain full independence. It also considers that the public administrations should promote the maintenance of effective and appropriate attention, through the coordination of resources and habilitation and rehabilitation services in the areas of health, employment, education, and social services, with the purpose of guaranteeing that people with disability are offered appropriate and varied services and programs in their own communities, in both rural and urban zones.

The most recent initiative in matters of autism promoted by the State has been the preparation of the Spanish Strategy on Autism Spectrum Disorders, approved by the Council of Ministers and sponsored by the Ministry of Health (2015). It is at present in a phase of development. This initiative seeks, among other questions, to encourage measures that promote the detection and diagnosis of ADS, appropriate educational attention, including the stages prior to the obligatory schooling of pupils with ADS, and evidence-based practices, especially in the case of professionals linked to early attention and infant education. The strategy also promotes the strengthening of a varied, appropriate, and specialized network of educational centers in all the territories that have the necessary means to provide individualized and quality education to pupils with ADS (professional profiles, ratios, resources, etc.). At the same time, it supports specialized, inclusive, and quality education for pupils with ADS, which is flexible and innovative in relation to the existing educational offer (procedures and choice of schools: combined education, ordinary education with support, specific classrooms in ordinary education and special education), in such a way that it responds to the individual needs and maximizes educational success,

personal development, and social inclusion. It moreover highlights the need to promote resources and support systems for people with ADS in adult life, guaranteeing their inclusion in working life, the possibility of developing an independent life outside the family home, legal protection of their rights, and full social participation in their own communities.

Overview of Current Treatments and Centers

At present, the map of ADS organizations in Spain is still incomplete, with provinces that have no specialized services, although associations have been created in some of them. In these situations, the majority of people with ADS with greater needs for support attend generalist centers for people with disabilities.

The proposal of family organizations in our country is to generate networks of support services that cover the needs of people with ADS throughout the life cycle and in all areas (diagnosis, early attention, schooling stage, training services, and support for the socioeconomic inclusion of adult persons in the workplace, at home, in leisure activities, etc.). In a parallel although not in a generalized manner, support services related to access to higher education and university especially have been established for people with ADS without the associated intellectual disability.

In relation to the models of intervention, there is quite widespread consensus over the need to incentivize actions based on educational objectives and the promotion of the strengths of people with ADS throughout their life.

The perspective of intervention is flexible, integrating the contributions of different psychoeducational models and, especially, those that offer greater scientific evidence: the TEACCH method, positive behavioral support, and different sociocommunicative methods.

Guaranteeing the quality of life for people with ADS and their families constitutes a clear objective for the majority of organizations and professionals, in such a way that the services are

oriented towards inclusion and the development of people in their own communities, as well as considering fundamental dimensions such as emotional and physical well-being, self-determination, social relations, etc.

If we center on the educational stage, the modalities of schooling that exist in Spain at present are as follows (Alonso and Cuesta 2017):

Ordinary Educational Centers

Ordinary classroom: In general, nowadays, in the field of Infant and Primary Education, a majority of children with ADS attend ordinary schools.

ADS classrooms located in ordinary educational centers: some centers, in their majority dependent on family associations, have classrooms located at ordinary centers (the number of specialized professionals at the center remaining unchanged).

Stable classrooms, an inexistent option in some autonomous regions. There is no official norm that regulates this approach to educational inclusion. The initiatives that have developed emerged from collaborative agreements between the provincial educational administrations, associations of autism, and ordinary centers where those classrooms are located. Under this modality, the pathway to inclusion in the ordinary classroom may be adapted in accordance with the strengths of each pupil. We can find stable classrooms in the three communities that are the object of our study. Stable classrooms may be found in the three communities that are studied in this paper.

Preferential centers of rehabilitation, in which the inclusion of the pupils with ASD is prioritized, because these centers have specialized support resources.

Combined or Mixed Schooling: permits the pupil to attend two different educational centers, generally one for special education and another for ordinary education, which makes it possible to combine the contribution of both centers. The times of permanence at each one will be established in an individual plan for each pupil, agreed between both centers.

Specific Special Education Centers: those in which all the classrooms are specifically for pupils with ASD.

General Centers of Special Education: welcome children with different types of disability.

With respect to adults, there are many organizations that have promoted support services, such as:

Day centers for adults, at which training programs are developed and the social and labor inclusion of people with ASD is promoted.

Employment support services, in which professional training is facilitated, intermediation with firms, labor practices, and incorporation in the workplace. Inclusion in the work place through supported employment has allowed the real incorporation of people with ASD in the world of work.

Different modalities of **housing services:** protected housing for people who require intermittent support, housing with permanent support, residences.

Leisure programs.

Programs that promote the practice of sports.

Support for access to higher education.

Many of the autism organizations have also specialized diagnostic services, which generally cooperate with the public services that are involved and that are complemented with programs of early attention.

The Spanish Autism Confederation (2009, 2016) has proposed a catalogue of support services for persons with ADS throughout their life, on the basis of the needs identified by organizations, professionals, and people with ASD. This document is called “Calidad de vida, hoy [Quality of life, today]” (Vidriales et al. 2015).

Overview of Research Directions

After the first large-scale investigation on autism in our country, conducted by GETEA Group

(Instituto de Salud Carlos III), another relevant initiative took place to dynamize this sector in Spain. This was the celebration of the *I Encuentro de Investigadores sobre Autismo* [First Meeting of Researchers on Autism], organized by the Centre of Applied Psychology of the Autonomous University of Madrid (Belinchón 2010). As follow-up to this meeting, a further initiative led to an up-to-date review of the different investigations that have contributed to greater understanding of autism from the perspective of neurobiology and genetics. The work also offers relevant information with practical implications for diagnosis and intervention (Alonso 2014).

Güemes et al. (2009) completed an investigation that evaluated the efficiency of psychoeducational interventions in the ASD.

Moreover, various investigations have been completed in relation to the needs of people with ASD and their families, with the purpose of promoting knowledge and raising awareness of the relevance of specialized support (Belinchón 2001; Belinchón et al. 2008; Saldaña et al. 2006).

One of the most relevant collaborative investigations into the quality of life of people with ASD has been promoted by Autism Spain in the project *Red para la Calidad de Vida* [Network for the Quality of Life]. This initiative in which 73 families, 70 people with ASD, and professionals have participated generated various results, among which is the design of an evaluation methodology of the specific quality of life for people with ASD, which contemplates the design of an information tool, ICalidad, that facilitates the evaluation process and includes a specific questionnaire (Vidriales et al. 2015).

Other investigations have referred to the needs emerging in relation to the support services: aging (Vidriales et al. 2016; Ruggieri et al. 2019), women with ASD, through the European project Autism in Pink, and the situation on the access of people with ASD to higher education and the university, in the framework of the European project Autism and Uni.

Participation in the European project ASDEU may also be highlighted, the objective of which is to analyze the social and economic costs of

autism; to review the existing programs on early detection and to develop proposals for their introduction and improvement; to prepare a plan for the improvement of professional training; to validate biomarkers associated with ASD; and to improve knowledge on diagnosis, comorbidity, and the effectiveness of care and support in adult life and in the elderly with a diagnosis of autism.

Finally, one of the more recent and relevant initiatives is the Bebe-Miradas Project, promoted by the Burgos Autism Association and the Miradas Foundation, consisting in the identification of signs in babies that warn of the presence of an Autism Spectrum Disorder (ASD), by means of “eye tracking,” referring them to specialized and specific intervention that prevents and minimizes the impact of the disorder in the development of the child.

Overview of Training

In parallel to the creation of groups of families and people with ASD, training and dissemination initiatives have started to emerge that to a great extent raise the awareness of public administrations and the development of professional practices that may have distanced themselves from psychoanalytic perspectives for the development of models based on a cognitive behavioral approach. A group of young professionals, linked to the first associations as technical advisors, were deeply involved in this process, such as Ángel Díez Cuervo and Ángel Riviére Gómez.

At present, the association of AETAPI professionals has been turned into a reference for training in autism care, through the biannual congresses that it organizes as well as thanks to other online training initiatives and one-day conferences on specialization that it has offered. The refresher course that this body promotes has seen over 250 participants in the three editions that it has celebrated up until today.

Likewise, AETAPI subscribes to and supports the training and specialization of professionals through collaborative agreements with different Universities (Autónoma de Madrid, Burgos, Sevilla, Zaragoza, and the Universidad Nacional a Distancia), and it collaborates in initiatives such

as the European IPA+ project *Inclusion of People with Autism in Europe. Towards a specialized training model for professionals*, in collaboration with other countries, in order to design a training curriculum that responds to the needs of professionals and the specialized organizations.

Social Policy and Current Controversies

The edition of the DSMV generated broad debate on the diagnosis of ASD among specialized professionals and the creation of a working group within the framework of AETAPI that conducts an exhaustive analysis of the implications that this new model had in the field of autism. One of the principal controversies was generated around the suppression of the diagnostic categories established in earlier editions, and especially one related with Asperger syndrome, because of its implications for the identification and the social recognition of the people who form part of this collective. At this time, agreement exists to continue gradually to include the terminology proposed in this new edition, without sidelining the concept of Asperger syndrome.

There are many challenges in the area of autism: increased prevalence generates new needs and the planning of different support services, from a flexible perspective, which contemplates diversity of demand in a collective characterized by great variability of degrees and manifestations of symptoms.

It is necessary to continue working to define, on the basis of the evidence contributed by science and experience, the most appropriate model to understand and to intervene in autism, burying interpretative proposals or “miracle cures” which are a cause of great concern to people with ASD and their families (AETAPI 2011; Ruggieri and Cuesta 2017).

The initiative of the government to promote the Spanish Strategy on Autism Spectrum Disorders has awakened great hope. It implies a step forward in the recognition of the rights of people who form part of this group and in the visibility of ASD as a condition in its own right, which generates specific needs and that makes the development

of specific support systems essential for the people who present them, throughout all stages of the life cycle.

Name and Degrees

Sparrow, Sara S. M.A. Ph.D. (May 9, 1933–June 10, 2010)

Major Appointments (Institution, Location, Dates)

- 2003 Professor Emerita, Yale University, Child Study Center and Department of Psychology; Senior Research Scientist, Yale Child Study Center
- 1989–2003 Professor of Psychology, Chief Psychologist, The Child Study Center, School of Medicine; Professor, Department of Psychology, Yale University
- 1986–1989 Professor of Psychology, Chief Psychologist, The Child Study Center, School of Medicine; Lecturer, Department of Psychology, Yale University
- 1977–1986 Associate Professor of Psychology, Chief Psychologist, The Child Study Center, School of Medicine; Lecturer, Department of Psychology, Yale University
- 1977–2002 Director, Psychology Internship Program, The Child Study Center, Yale University
- 1974–1977 Assistant Professor, The Child Study Center and the Department of Psychology; Chief Psychologist, The Child Study Center, Yale University
- 1974–1975 Visiting Professor, Child Development Department, Connecticut College, New London, Connecticut
- 1972–1974 Research Associate and Lecturer, Department of Psychology and The Child Study Center, Yale University
- 1972–1973 Acting Chief Psychologist, The Yale Child Study Center, Yale University
- 1970–1972 Research Associate, Department of Psychology, Yale University
- 1969–1970 Research Staff, Department of Psychology, Yale University
- 1968–1969 Postdoctoral Fellow, Department of Psychology, Yale University
- 1965 Director, Summer Speech Clinic, Speech Department, University of Florida
- 1962–1964 Coordinator, Speech and Hearing Program, Orange County Schools, Orlando, Florida
- 1958–1961 Speech Therapist, Orange County Schools, Orlando, Florida

Major Honors and Awards

- 2010 Lifetime Child Study Center Service Award
- 2009 Edgar Doll Award for “her outstanding research and sustained contributions to the understanding of intellectual and developmental disabilities,” APA Toronto
- 2009 Distinguished Career Award, International Neuropsychology Society, Atlanta, GA
- 2008 Outstanding Alumnus of the Year, University of Florida, College of Public Health and Health Professions, Gainesville, FL
- 2006 Distinguished Alumnus Award, University of Florida, College of Public Health and Health Professions, Gainesville, FL
- 2004–2005 President, Division 33, Mental Retardation and Developmental Disabilities, American Psychological Association
- 2003–2004 President-Elect, Division 33, Mental Retardation and Developmental Disabilities, American Psychological Association
- 2002–2003 President-Elect Designate, Division 33, Mental Retardation and Developmental Disabilities, American Psychological Association
- 2002 Career Scientist Award, The American Academy on Mental Retardation
- 2000–2002 National Research Council, Committee on Disability Determination for Mental Retardation, Washington, DC
- 1998 Invited Participant, NICHD Workshop on Measurements of Clinical Outcome, Surrogate Endpoints, and Diagnostic Markers in Pediatric Drug Trials. September 24–25, 1998 Rockville, MD
- 1998 Professional Achievement Award, 2nd Annual Learning Disorders Symposium, H.E.L.P. Group. September 18–19, 1998. Sherman Oaks, CA
- 1994–1997 Elected to the Board of Governors, International Neuropsychological Society
- 1993–1999 Coeditor, Journal of Child Neuropsychology
- 1993 Cochairperson, Human Resources Development Task Force, Center for Health and Human Services
- 1992 National Advisory Board: “Development and Implementation of a Plan to Assess the

Neurodevelopment of Infants and Children Exposed to Drugs in Utero." NIMH

1990 Facilitator: National Conference on Implementing Public Academic Linkages for Clinical Training in Psychology. NIMH and APA, Dec. 10–12, 1990

1990 Project Review Committee, National Institute of Mental Health Training Grants

1989 "National Conference on Clinical Training for Multidisciplinary Services for Seriously Emotionally Disturbed Children and Adolescents." Georgetown University Leavey Conference Center, Washington, DC

1989 Member Consensus Development Panel, National Institutes of Health, Treatment of Destructive Behaviors in Persons with Developmental Disabilities

1988 Fellow, American Psychological Association (Div. 33)

1987 Review Panel Member, Research Project "The Higher Cerebral Function Disorders in Children," NICHD, Washington, DC, 1987, 1988, Chairman 1989–1994

1985–1986 Chairman, Quality Review Committee, Connecticut State Planning Council on Developmental Disabilities

1984 Fellow, American Psychological Association (Div. 12)

1984 First Recipient, Connecticut Psychological Association "Award for Distinguished Effort by a Connecticut Psychologist, Utilizing Psychological Knowledge and Skills, Which Has Made Contribution to the Welfare of the Public," for development and publication of revised Vineland Adaptive Behavior Scales (1984, 1985), at Fairfield University, December 7, 1984

1984 Project Review Committee, National Institute of Mental Health Training Grants

1982 Elected to American Academy of Mental Retardation

1980–1986 Member, Connecticut State Planning Council on Developmental Disabilities (appointed by Governor).

1971–1972 Committee on Book Reading, International Reading Association

1970 Who's Who in American Women

1968 American Men of Science

Landmark Clinical, Scientific, and Professional Contributions

Vineland Adaptive Behavior Scales, Second Edition (Vineland-II)

Short Biography

Dr. Sara S. Sparrow was a North American psychologist, whose work focused on children and their developmental trajectories, ranging from intellectual giftedness to severe mental retardation. Dr. Sparrow made contributions to the fields of child neuropsychology and developmental disabilities across a wide range of diagnostic groups of children and also across cultures. She was particularly engaged with children with autism spectrum disorders, intellectual disabilities, and learning disabilities. Dr. Sparrow trained many mental health professionals at the doctoral and postdoctoral levels; she was the founder of the child psychology internship program at the Yale Child Study Center. She was also an influential and highly valued teacher and clinical supervisor within various Yale University programs. Several generations of her former trainees work all over the world, leading clinical science programs for children with special needs.

Dr. Sparrow's landmark contribution was the Vineland Adaptive Behavior Scales, Second Edition (Vineland-II), which is one of the most broadly used psychological assessment instruments used throughout the world. She was the senior author and a devoted promoter of this instrument. The Vineland is used extensively in clinical, educational, and research settings as a means of evaluating individuals' personal and social skills in everyday living. It was the first life-span, norm-referenced instrument measuring adaptive behavior in multiple domains. The Vineland is a particularly critical diagnostic tool in the assessment of individuals with intellectual and developmental disabilities, including autism spectrum disorders.

A native of Minneapolis, Minnesota, Dr. Sparrow graduated summa cum laude from

Montclair State College in New Jersey in 1958 and received her professional degrees from the University of Florida, M.A., in speech pathology in 1962 and Ph.D. in clinical psychology/clinical neuropsychology in 1968. She went to Yale in 1968 as a postdoctoral fellow in the Department of Psychology. She joined the department's research staff the following year, then served as acting chief psychologist at the Child Study Center in 1972–1973. She was appointed to the rank of assistant professor in 1974, associate professor in 1977, and full professor in 1986.

Dr. Sparrow's contributions to psychology included more than 120 articles and book chapters in the fields of child neuropsychology, learning disabilities, test development, and adaptive behavior in a broad range of child psychiatric conditions. Additionally, Dr. Sparrow maintained active clinical practice within the Yale Child Study Center, where she was Chief Psychologist from 1997 to 2002, and then continued working with patients and conducting research as Professor Emerita of Psychology and Advisor to the Yale Academic Skills Clinic until her untimely death. Beyond Yale, Dr. Sparrow assumed leadership roles in psychology at the national level. She served as President of Division 33 of the American Psychological Association (Intellectual and Developmental Disabilities), was a member of the National Research Council (National Academy of Sciences) Committee on Disability Determination for Mental Retardation, and was cofounder of the *Journal of Child Neuropsychology*.

Dr. Sparrow's scientific contributions have been recognized through numerous awards including Alumnus of the Year by the College of Public Health and Health Professions at the University of Florida; she and her husband, Dr. Domenic Cicchetti, shared the first Scientific Achievement Award given by the Connecticut Psychological Association; she was a recipient of the Edgar Doll Award from Division 33 of the APA which is the division's highest recognition of outstanding scientific contributions to the field of intellectual and developmental disabilities; and in

2002 Dr. Sparrow received the Career Scientist Award from the American Association of Mental Retardation for her lifetime contributions to the field.

Speaker Versus Listener-Oriented Disfluency

Paul Edward Engelhardt

School of Psychology, University of East Anglia, Norwich, Norfolk, UK

Definition

Deficits in pragmatic language and social communication are characteristic of verbal individuals with autism spectrum disorders (ASD). Disfluencies are pauses and interruptions, which

break the continuity of speech outputs. Disfluencies are often classified into different categories, primarily including pauses, repetitions, and repairs. These disfluencies are produced by all people in the normal course of speaking, and estimates place their occurrence at 6–10 per 100 words produced. Crucially, these disfluencies are distinguished from “dysfluency,” which refers to pathological fluency issues (i.e., stuttering or stammering). However, it is important to note that several reports have indicated stuttering-like disfluency in some individuals with ASD (see Scott 2015).

Disfluencies may serve pragmatic purposes in that they cue problems within the speaker for the benefit of the listener. Speaker-oriented disfluencies are thought to be due to speaker-internal factors (i.e., difficulties associated with the process of planning and producing language). In contrast, listener-oriented disfluencies are believed to be produced in interactive dialogue, specifically for the listener and for the benefit of communicative exchanges/efficiency. This entry provides a review of existing evidence relating to speaker- and listener-oriented disfluency in ASD. Evidence for speaker-oriented (or speaker-internal causes of) disfluency could come from different sources. However, the pattern one would expect is that there should be negative correlations between rates of disfluency and speaker-internal variables. In short, higher rates of disfluency would be associated with lower ability individuals, including individual differences variables, such as executive functions, intelligence, and also higher ASD symptom severity. In contrast, listener-oriented disfluency should show positive correlations between higher social-communication abilities, and also higher abilities in individuals differences variables. The debate between speaker- and listener-oriented disfluency has been applied to ASD, given that individuals with ASD tend to take an egocentric approach to dialogue and as such should be less likely to produce disfluencies that are specifically helpful for listeners in conversation.

Historical Background

It has long been known that language impairments are fundamental to ASD (e.g., Rutter 1970). There has been a great deal of recent interest in the production of disfluency by individuals with high-functioning forms of ASD. However, this line of research has its beginnings in the 1970s, and the first report of excessive disfluency production in ASD was provided by Simmons and Baltaxe (1975). Those authors found that approximately half of their sample showed hesitations, repetitions, prolongations, and nonfluencies. (Definitions and examples of these categories were not provided.) Abnormalities in the fluency of speech outputs in the 1970s were classified as faults in rhythm, and tightly linked with abnormalities in prosody. To provide some historical and current context, a histogram is provided showing the number of studies examining disfluent speech in ASD over time (see Fig. 1). This includes PhD dissertations, conference presentations, and published research studies. As can be seen in the figure, a clear uptick occurred approximately 15 years ago.

Current Knowledge

This review follows the standard disfluency classification scheme from psycholinguistics (i.e., filled pauses, unfilled pauses, repetitions, repairs, and “other”) and presents results of each type of disfluency separately. The main focus is the debate about which forms of disfluency are speaker-oriented and which are listener-oriented. The latter (i.e., communicative purposes) are the type hypothesized to be produced less often in individuals with ASD, due to their impairments in socially oriented pragmatic language use (De Marchena and Eigsti 2016; Tager-Flusberg et al. 2005). These impairments, specified in the DSM-5, include failure of normal back-and-forth conversation and failure to initiate or respond to social interactions. However, the criteria also specify that individuals with deficits in social communication but not

Speaker Versus Listener-Oriented Disfluency,

Fig. 1 Histogram showing frequency of studies related to disfluent speech in ASD

otherwise meeting the criteria for ASD should be screened for social (pragmatic) communication disorder, a recent addition to the DSM-5, which overlaps substantially with ASD diagnostic criteria. The conversational profile for social-communication disorder includes difficulties following social rules of communication in conversation, which leads to problems (1) communicating effectively and engaging in a social manner, (2) matching speech outputs to context, (3) rephrasing when misunderstood, (4) making appropriate inferences, and (5) understanding non-literal language. These kinds of issues are all related to socially oriented *pragmatic* language use.

With these general pragmatic language issues in mind, it is important to situate disfluency production within a theoretical context. The first theoretical context is the process of language production. Many prominent models of production assume a stage-based architecture. For example, Levelt (1989) proposed a three-stage model consisting of conceptualization, formulation, and articulation. The basis of any model of production is the conversion of nonlinguistic thoughts into the articulated words and syntax structures of speech output. Most models also assume some type of monitoring mechanism, which is responsible for detecting faults or problems in pre-articulated speech plans. As mentioned previously, speaker-oriented disfluencies are likely related to difficulties arising in one or more stages of production. Difficulties could arise from a number of causes (e.g., planning

problems, memory retrieval difficulty, lapses of attention, or individual difference variables). For example, if lemma selection (choosing which words to convey the intended message) involves inhibitory control, then we should observe individual differences in inhibition relating to rates of disfluency. The second theoretical context involves theories of ASD, which are surprisingly not often considered in disfluency studies. If interactive dialogue relies on taking the listeners' needs into account or being overtly helpful to the listener via disfluency, then Theory of Mind has implications for listener-oriented issues (Baron-Cohen et al. 1985). In contrast, if disfluency production is more related to individual differences in executive functions, then theories of Executive Control in ASD become relevant for speaker-oriented (or speaker-internal) issues (e.g., Hill 2004).

With this theoretical context in mind, a couple of caveats should be noted. The first is that despite existing disfluency studies examining children, adolescents, and adults, there is currently not sufficient evidence to determine how disfluency production changes over the course of development. Therefore, in the following review, there is no discussion of developmental effects. The second is that studies have used both controlled and more naturalistic speaking situations, and again, there are limited studies of each type, which limits firm conclusions about how task differences affect disfluency production. Thus, task differences are only highlighted in the event of conflicting and/or mixed findings.

Filled Pauses

Many studies have focused on the production of “fillers,” which in English, primarily constitute “UMs” and “UHs.” The production of filler-type disfluencies is believed to arise from difficulties experienced by the speaker, for example, in thinking or planning what one wants to say (Clark 1994). In short, the speaker experiences a problem, they know it, and in response, produce *UM* or *UH* to signal the listener. Therefore, fillers serve communicative purposes in interactive dialogue. Past studies (e.g., Clark and Fox Tree 2002) have suggested that speakers produce fillers as a collateral signal to the listener that they are not finished speaking, want convey some uncertainty, or signal an upcoming delay (i.e., they need more planning time).

Research has shown that individuals with high-functioning autism (HFA) produce fewer fillers compared to controls, and given the social-pragmatic deficits in ASD, fillers are thought to provide evidence of listener-oriented disfluency. *UMs* tend to occur at the beginning of prosodic phrases and are typically followed by longer pauses than are *UHs*. Some studies (e.g., Lake et al. (2011) and MacFarlane et al. (2017)) did not differentiate *UM* and *UH* but did report fewer filled pauses in ASD. In contrast, Suh et al. (2014) did not find significant group differences (ASD vs. control) in a monologue story telling task. However, in a key study, Irvine et al. (2016) found that *UM* production differentiated groups, but *UH* did not. Moreover, *UM* rate was correlated with ASD symptom severity, but did not correlate with other key individual difference variables (age, verbal IQ, nonverbal IQ, language ability, or executive function). Further studies have confirmed this dissociation between *UM* and *UH* in ASD (e.g., Gorman et al. 2016). A key advancement in filler production was the calculation of *UM* to *UH* ratio (i.e., $UM/(UM + UH)$). On the basis of the evidence, it has been concluded that *UM* production reflects social-communication skills and is therefore a clear listener-oriented type of disfluency (see Table 1, for mean *UM-UH* ratios across studies). Moreover, low *UM* production has even been postulated as clinical-diagnostic marker of ASD, specifically

Speaker Versus Listener-Oriented Disfluency, Table 1 Results for *UM/UH* ratio across studies

Study	Control	ASD
Gorman et al. (2016) (estimated from Fig.)	.77	.40
Heeman et al. (2010) (turn initial)	.69	.47
Heeman et al. (2010) (utterance initial)	.63	.30
Heeman et al. (2010) (utterance medial)	.80	.40
McGregor and Hadden (2018)	.92	.70
Parish-Morris et al. (2017) (boys)	.78	.56
Means	.77	.47

in boys with the disorder (McGregor and Hadden 2018). Females with ASD, in contrast, were not different than controls in *UM-UH* ratio. However, this gender finding should be replicated before firm conclusions are drawn.

Two additional findings are worth highlighting. The first finding relates to the location of filled pauses. Heeman et al. (2010) analyzed the location of filled pauses under the assumption that location may reveal information about their function. Filled pauses were coded as to whether they occurred turn initially, utterance initially, or mid-utterance. *UH* rates were similar across all three positions. However, participants with ASD used *UM* less frequently across all three positions. *UMs* were half as frequent at turn-initial positions, one-fifth as frequent at utterance-medial positions, and utterance-initial position fell in between. The second finding relates to speaking task. The highest rates of filled pauses occurred in conversation, as compared to a describing task and a play task. Crucially, *UMs* seemed to vary by position and task type, but the differences between ASD and controls remained significant, whereas *UHs* showed no difference between groups despite some variance in position and task type. It is currently unknown how much of the task differences are associated with the face-to-face nature of the speaking situation, but filled pauses are typically not produced in monologue speaking situations. Interestingly, Heeman et al. also reported no significant differences in the length of pauses following fillers

between the two groups. In the psycholinguistic literature, it has been argued that *UM* is used as a signal of an upcoming long delay and *UH* an upcoming short delay (Clark and Fox Tree 2002).

In summary, individuals with ASD do not produce filled pauses, in particular, *UMs* as frequently as do controls. Estimates suggest that *UMs* are produced approximately 2-to-1 over *UHs* in controls, but approximately 1-to-1 in ASD. Thus, it seems that individuals with ASD tend to produce unfilled pauses instead of filling pauses with *UM*. Moreover, differences in filled pause production do not seem to be related to age, more general language abilities, IQ, or executive functions. Several studies have examined whether *UM* usage is correlated with ASD symptom severity. Two studies reported significant negative correlations (Irvine et al. 2016; Parish-Morris et al. 2017), and two have not found a significant association between *UM* production and ASD symptom severity (Gorman et al. 2016; McGregor and Hadden 2018).

Unfilled (or Silent) Pauses

Several studies have also examined the production of unfilled or silent pauses. Both Lake et al. (2011) and Shriberg et al. (2001) reported higher rates of unfilled pauses in ASD. One potential issue with unfilled pauses is the criterion of what counts as an unfilled pause. For example, Lake et al. defined unfilled pauses as 3 sec or longer, whereas Engelhardt et al. (2017) used 250 ms. This may or may not be a problem, as research has only begun to examine the distributions of the length of pauses between ASD and controls to determine whether one has a tendency to produce particularly long or short pauses. In general, the distributions of pauses (in controls) are positively skewed (see Fig. 2 for an example). In monologue production tasks, the group effect (ASD vs. control) on unfilled pauses appears to turn on how groups are matched. Age and gender matched groups tend not to show differences. The Engelhardt et al. study utilized a memorize-and-repeat sentence production paradigm, which relied heavily on memory. Their results showed a

Speaker Versus Listener-Oriented Disfluency,

Fig. 2 Histogram showing an example of the length and frequency of unfilled pauses in typically developing adults

group effect (ASD vs. unmatched controls) over and above variance accounted for by working memory (i.e., working memory ability and ASD status were both significant predictors of unfilled pauses).

Thurber and Tager-Flusberg (1993) also investigated unfilled pauses, but their conclusion was that individuals with ASD expended less effort in constructing narrative discourses (i.e., in a story re-telling task). As a result, they found the opposite pattern from previous studies. That is, ASD participants produced fewer nongrammatical pauses, because their stories were shorter, less complex, and had less lexical diversity, which resulted in between-group differences in cognitive load. In contrast, grammatical pauses (i.e., pauses produced at major syntactic boundaries or points of emphasis in speech) were not significantly different between groups.

Heeman et al. (2010) examined the length of pauses between conversational turns under the hypothesis that individuals with ASD would have less awareness or concern about social cues to minimize silence, or alternatively, whether longer pauses would be due to slower planning and overall slower response times. Thus, they believed that pauses could be due to either speaker-internal factors or poor social-pragmatic communication skills. Their results showed mean pause lengths of 876 ms (control) vs. 1115 ms (ASD). Similar between-group mean differences were observed, specifically following questions. Wiklund and Laakso (2019) also reported longer pauses within a conversational turn. Perhaps more interestingly, Heeman et al. also examined the length of pauses depending on *activity type*. In conversation, the difference between groups following a question was not significant, but in a play activity, there were significant differences and the mean difference between groups was much higher (mean difference of 569 ms). These findings were independent of threshold, as the authors were able to determine the length of silence between all turns in the conversation. However, this study did not control for individual differences measures, and so, to the extent that these data shed light on the speaker- vs listener-oriented issue remains to be determined. That is, studies

examining the length of pauses in dialogue did not consider individual difference variables or ASD symptom severity.

At present, most evidence suggests that unfilled pauses are produced more frequently in individuals with ASD, but at the same time, this effect also seems to be affected by (group) matching variables, which suggests speaker-oriented production issues. Clearly, more work is needed to examine pause frequency differences and length of pause differences based on speaking task. Also, given the findings of Thurber and Tager-Flusberg, more attention concerning the type of pause is warranted.

Repetitions

The first report of abnormal repetitions was provided by Simmons and Baltaxe (1975). They observed high rates of repetitions in four of their seven children with ASD. Other studies have reported similar findings (Lake et al. 2011; Shriberg et al. 2001; Suh et al. 2014), but one study found no significant differences in repetitions (Thurber and Tager-Flusberg 1993). One key issue with repetitions concerns the relationship between repetitions and verbal IQ. Engelhardt and colleagues across a range of (non-ASD) studies have shown that differences in repetitions are highly related to verbal IQ (e.g., Engelhardt et al. 2019; Engelhardt et al. 2013). In an ASD study, when verbal IQ was covaried, the group effect (ASD vs. control) was no longer significant (Engelhardt et al. 2017). This study highlighted a key issue with respect to study protocols and matching of groups on individual difference variables. Verbal IQ is a particularly interesting individual difference measure with respect to ASD because verbal IQ in ASD often shows a large range. That is, a fair number of individuals with ASD have higher verbal IQ than controls, and others, depending on the overall severity of ASD, are generally lower functioning and have lower verbal IQ. At this point, it seems that the tendency to repeat words and phrases is likely due to a specific speaker-internal factor and that if differences in verbal IQ are taken into account, then individuals with ASD do not show higher rates of repetitions than do controls.

It is important to bear in mind, however, that the proportion of variance explained by verbal IQ is typically between 25% and 50%, and so, other (unknown) factors likely contribute to variance in repetitions. At this point, it is also unclear why verbal IQ is related to repetitions. It is also important to note that no study to date has systematically examined repetitions and other language ability measures (e.g., Clinical Evaluation of Language Fundamentals, which assess expressive and receptive language abilities).

Repairs

Repairs are also referred to as revisions and false starts in the literature. With repairs, the speakers stop speaking and then restart with a new word or phrase. As such, these disfluencies reveal instances in which speakers correct, clarify, or elaborate on the content of their output. This type of disfluency presents the most complicated picture in terms of the speaker- vs. listener-oriented debate, because repairs have been shown to be associated with many different individual difference variables. There are also mixed findings in the literature concerning whether individuals with ASD produce more repairs than do controls. However, the majority of studies show that individuals with ASD do produce more repairs (De Marchena and Eigsti 2016; Engelhardt et al. 2017; Shriberg et al. 2001; Sisskin 2006; Suh et al. 2014). The one study which concluded that repairs are a listener-oriented form of disfluency did so simply on the basis that individuals with ASD produced fewer repairs. In a later study, Engelhardt et al. found the opposite, individuals with ASD produced more repairs than controls. Engelhardt et al. reported that the increased tendency to produce repairs was associated with several Autism Quotient subscales (i.e., autism symptom severity). In addition, the group on repair findings held even when covarying individual differences and demographic variables, and so, with the exception of Lake et al., it appears that more repairs are produced by individuals with ASD.

Two additional points are worth mentioning here. The first is the notion of self-corrections. Obviously, certain types of errors in the content

of speech will lead to conversational breakdowns via the risk of mis-communication. Therefore, the only way to “rescue” a listener-oriented conclusion about repairs is to assume that higher rates of repairs are due exclusively (or largely) to situations in which the speaker needs to correct an outright mistake. Similar points about self-corrections were made by both De Marchena and Eigsti (2016) and Wiklund and Laasko (2019). The former found higher rates of repairs in a shared (common ground) condition in controls compared to ASD, suggesting that individuals with ASD did not adjust, correct, or clarify when it was appropriate to do so. Wiklund and Laasko argued that individuals with ASD showed marked deficits in linguistic and morpho-syntactic abilities, but were able to monitor sufficiently well these deficits and to correct in the event of possible misunderstanding for listeners. This again suggests some listener-oriented motivation for the production of repairs, but obviously, more research is needed to definitively understand whether some repairs may have a listener-oriented function.

The second point is that rates of repairs differ based on the speaking task. For example, MacFarlane et al. (2017) found that ADOS dialogue was a much stronger predictor of disfluency rates compared to telling a story from a book, despite not observing differences between ASD and controls. However, MacFarlane et al. included some additional detail about the nature of the repairs. They distinguished whether the repair was a true error (e.g., *turn left...right*), what MacFarlane et al. referred to as a “revision,” or whether it involved a deletion (e.g., *my old dog...my dog.*) or insertion (e.g., *my dog...my old dog.*) of linguistic material. They also classified false starts (e.g., *Dogs...My friend likes dogs.*) as a separate category. This more detailed classification scheme may prove informative in future studies to elucidate the specific form of repairs produced by individuals with ASD, as well as shedding light on the speaker- vs. listener-oriented issue.

In summary, evidence clearly points to individuals with ASD producing more repairs than controls. Also, there is no concrete evidence at this

point to suggest that repairs are a listener-oriented form of disfluency. Instead, the tendency to produce repairs is related to many different types of individual difference variables and also to ASD symptom severity.

Other (Interjections, Prolongations, and Atypical Disfluency)

“Other” forms of disfluency have received much less empirical investigation compared to the types reviewed above in both the clinical and psycholinguistic literatures. This is partially due to the fact that they are produced much less frequently overall and also they do not fit well within the typical classification schemes and as such, are classified as “other.” Obviously, interjections (*I mean, you know*, etc.) could be communicatively beneficial in terms of signaling something important to a listener. No study to date has examined the production of interjections in ASD, but Heeman et al. (2010) did analyze “discourse markers” and “acknowledgments.” Prolongations (e.g., *theeeeeee* vs. *the*) have been noted in the psycholinguistic literature, as a mechanism in which the speaker “buys” themselves more time, presumably due to difficulty with an upcoming element in the speech stream (Arnold et al. 2004). However, again, no study has examined the production of prolongations in ASD.

Atypical disfluencies are quite interesting: They were noted in the original studies in the 1970s but have rarely been classified and/or observed in later studies (cf. Plexico et al. 2010; Scaler Scott et al. 2014). Some common examples are final syllable repetitions (e.g., *speech. . .eech, animal. . .mal*) and stuttering-like disfluency, including part-word perseverations (e.g., *d.d.d.d. d.dog*), single syllable repetitions (e.g., *I.I.I.I*), and dysrhythmic blocks. Readers interested in atypical disfluency and cluttering (i.e., excessively fast speech that overloads the production system) and the incidence rates of these things in ASD should consult Scott (2015), Scaler Scott et al. (2014), and Sisskin (2006).

Summary

This review has focused on how individuals with ASD show differences in disfluency in their

speech outputs compared to controls. Some of these can be clearly linked with speaker-internal factors and some with more listener-oriented functions. It is also important to note that there are several reports that suggest that some types of disfluency are associated with comprehension problems for listeners, in particular, repairs (see Wiklund and Laasko 2019), which suggests that the production of disfluency can be communicatively problematic. Filled pauses provide the clearest example of listener-oriented disfluency, and here, the research shows that individuals with ASD produce fewer *UMs* than do controls. The rate of *UHs* is not affected. Unfilled pauses are produced more frequently in individuals with ASD, and particularly, in unmatched samples. The evidence tends to indicate that unfilled pauses are related to speaker-internal factors and as such, are likely a speaker-oriented form of disfluency. Likewise, repetitions are highly associated with individual differences in verbal IQ, and at this point, not linked to ASD (cf. Suh et al. 2014). Finally, repairs have been linked with executive functions and individual differences in IQ. However, they are also produced more frequently in individuals with ASD. This may be due to more basic language-related impairments. The strength of the relationships between repairs and individual difference variables and ASD symptom severity are much more variable (perhaps due to differences in task demands) as compared to the other types of disfluency.

Future Directions

Below are two “general” future directions (points 1 and 2) which are based on re-occurring themes arising throughout this review. I have also highlighted two “specific” future directions (points 3 and 4) which take the study of disfluency in ASD in novel and exciting new directions.

1. A recurring theme throughout the review was the differences in task demands associated with the speaking situation in which disfluencies were analyzed. For example, does the task involve monologue or dialogue and is the

speech scripted or naturalistic. Many studies have examined disfluencies produced in ADOS assessments, which is an excellent source of data given its widespread use and semi-structured nature. Relatedly, what are the cognitive load differences associated with the speaking task? It is likely that overall rates of disfluency (and type of disfluency produced) will differ depending on the speaking situation and task demands. Further studies are needed to assess disfluency production when speaking with and without eye contact and about emotional topics.

2. With respect to control variables and the matching protocols between groups (ASD vs. control), further research is needed to determine which variables are key so that confounds can be avoided. Past research suggests that demographics (age, gender), individual difference variables (specifically verbal IQ, nonverbal IQ, executive functions), language abilities, and comorbid disorders are all important in some situations. These issues are especially important for speaker-oriented disfluencies. There are also a number of issues that need to be investigated concerning the relationship between verbal IQ and repetitions.
3. A recent study has linked disfluency production to particular genetic signatures in mothers who had a child with a developmental disorder (Klusek et al. 2018). To establish a relationship between an etiologically more basic (causal) factor and disfluent speech is an exciting avenue of research. It remains to future research to determine how these genetic differences are linked to structural-functional brain abnormalities, resulting in a behavioral profile characterized by fluency issues.
4. The time and cost associated with disfluency analysis is immense. It requires hand coding of the data, typically by a research team, in order to gain the requisite inter-rater reliability, especially for more subjective forms of disfluency (e.g., unfilled pauses). If we are to take McGregor and Hadden's suggestion of using disfluency as a clinical-diagnostic marker of ASD seriously, the field needs to simplify, speed, and reduce cost. Therefore, automated

annotation of speech samples is critical. Currently, automated disfluency analyses only detect disfluency generally, not specific categories or subcategories (i.e., filled pauses, repetitions, repairs, etc.) (see Morley et al. 2014).

Special Education

Pamela Brucker

Special Education and Reading, Southern
Connecticut State University, New Haven, CT,
USA

Definition

Special education is a broad term that refers to a variety of direct instructional and related services that are available for students ages birth–21 who meet specified criteria for eligibility under the Individuals With Disabilities Education Act (IDEA). These services are designed to give the eligible student a “free and appropriate public education.”

Special Education Service Utilization in ASD

Christin A. McDonald
Nationwide Children's Hospital's Center for
Autism Spectrum Disorders, Westerville, OH,
USA

Definition

The investigation of what special education services (e.g., speech, occupational, physical therapies; 1:1 aide support; behavior support plans; classroom placements; and academic supports) children with autism spectrum disorder (ASD) currently access.

Historical Background

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by symptoms of social-interaction and social-communication impairments and restricted and repetitive interests and behaviors (American Psychiatric Association [APA] 2013). These prominent features of ASD often limit students' functioning in schools (Wei et al. 2014). In addition to these core diagnostic symptoms, many children with ASD present with problem behavior (e.g., noncompliance, aggression, and disruptive behaviors; Ashburnere et al. 2010), and other associated difficulties. As a result, many children with ASD receive long-term intervention, often in the school setting (Kang-Yi et al. 2016). Generally these services in the schools address symptoms and behavior that interfere with overall learning and functioning in the school setting (Kang-Yi et al. 2016), which may include academic, behavioral, and therapeutic supports (Kang-Yi et al. 2016; McDonald et al. 2019; Wei et al. 2014; White et al. 2007). Given the amount of time spent in the school setting, access to services in schools is critically important for children with ASD (McDonald et al. 2019; Narendorf et al. 2011) and may be the most accessible service option (White et al. 2007). In addition, services in the schools often lead to service provision outside of the school setting (White et al. 2007).

Prevalence estimates of children with ASD have documented an increase of 29% between 2008 and 2010, with the majority of this increase attributed to the growing number of children with ASD without intellectual disability (Center for Disease Control and Prevention [CDC] 2014, 2016). For example, the CDC (2016) documented that in 2012, the number of students identified with ASD with average or above average cognitive ability had risen to 43.9%. Due to the growing number of children with ASD in the schools, special education services are challenged (Yeargin-Allsop et al. 2003).

According to the USDOE (2017) Annual Report, 9.1% of the children ages 6–21 accessing special education services were served under the special education classification of Autism.

However, the number served under the classification of Autism may be misleading and represent an underestimate of the number with a clinical diagnosis of ASD served in special education (CDC 2014; McDonald et al. 2019; Rubenstein et al. 2018). For example, Rubenstein et al. (2018) examined special education trends of 8-year-olds ($n = 6010$) who had been diagnosed with ASD from 2002 to 2010, and discovered that more than 36% of these children did not receive special education eligibility under the classification of Autism during each surveillance year. These findings are a low estimate compared to those reported by the CDC (2014), who found that between 30% and 69% of students diagnosed with ASD received special education services under the classification of Autism. However, Rubenstein et al. (2018) also noted that the number of children accessing special education services via a classification of Autism increased by 3.6 percentage points from 2002 to 2010, with the greatest proportional increase documented amongst Hispanic students diagnosed with ASD.

Given these findings, many students clinically diagnosed with ASD receive special education services under a different educational classification than Autism (CDC 2014; McDonald et al. 2019; Rubenstein et al. 2018; Sansosti 2010; Toomey et al. 2009). These other special education classifications encompass such options as Other Health Impaired (OHI), Speech and Language Impairment (SLI), Emotional Disturbance (ED), Specific Learning Disability (SLD), and Multiply Disabled (MD; CDC 2014; Toomey et al. 2009). McDonald et al. (2019) conducted a survey of special education classifications of children with ASD without ID and found that the majority of children with ASD without ID were classified under Autism (56%), followed by OHI (27%) as the second largest category of classification. This is in contrast to the findings of Toomey et al. (2009), who found that children with ASD without ID were most frequently classified under OHI, while only 17.6% were classified under the Autism category. While the percentage of children classified under Autism for special education services may vary, the distribution of children diagnosed with ASD among variable special

education classifications continues to indicate that the unique features and needs of students should be examined when designing specific academic, social, and behavioral interventions. This is in contrast to school personnel relying on the specific special education category to guide intervention decision-making (Toomey et al. 2009).

Current Knowledge

Given the number of children with ASD accessing special educational services, more information is needed regarding how they are accessing these services. Zuckerman et al. (2017) assessed service use as well as documenting diagnostic age and delay among 722 elementary-school children with ASD, using the CDC's Survey of Pathways to Diagnosis and Services data. Of this sample, 63% of the children with ASD demonstrated a functional delay. Zuckerman et al. (2017) found that children who were diagnosed later (after 4 years of age) were less likely (72%) to access school-based services than peers who had been diagnosed before the age of 4 (90%). Children were diagnosed later were also more likely to take psychotropic medications (Zuckerman et al. 2017). Further, as time-to-diagnosis increased for those children with ASD with functional delays, Zuckerman et al. (2017) found that these children were less likely to receive school-based therapies. Finally, Zuckerman et al. (2017) expressed concern that nearly a quarter of elementary school-aged children with ASD did not receive school-based services.

Of those who have been accessing special education services in the schools, there has been a recent trend of placing students with ASD in inclusive classrooms in the general education setting (Lauderdale-Littin et al. 2013; Martins et al. 2014). For example, the United States Department of Education (USDOE 2012) has reported that between 2004 and 2010, the number of students with ASD attending public schools has doubled. In addition, there was a 244% increase of students with ASD in full-inclusion classrooms from 1992 to 2006 (USDOE 2010). Researchers have found that students with higher cognitive and social

abilities were more apt to be placed in inclusive settings (Lyons et al. 2011; White et al. 2007). Conversely, students with ASD with lower IQs, lower adaptive behavior skills, and higher ASD symptoms were likely to be placed in more restrictive special education settings (Eaves and Ho 1997; White et al. 2007).

Supporting the trend toward inclusion, recent studies have reported a positive impact on the level of social engagement of students with ASD in the inclusion setting (Sansosti and Sansosti 2012). For example, studies examining subgroups of children with ASD without ID have demonstrated that they engage in increased social interaction in the mainstream classroom (Dahle 2003), have larger networks of friends, or are included in peer activities at the same rate as their same-age peers without disabilities (Chamberlain et al. 2007). Others note that an inclusive placement alone may be insufficient to fulfill the social and academic needs of children with ASD (Leyser and Kirk 2004; Sansosti 2010). In addition, special education placement only describes a minute portion of special education service use. Therefore, further examination of services used within the parameters of special education is warranted.

In a study of 101 children with ASD without ID, White et al. (2007) examined relationships between child demographic factors and special education, and found that children with ASD without ID with lower cognitive and language abilities were more likely to receive special education services. In general, service use was highest in the third and fourth grades, and lowest in eighth grade. Further, White et al. (2007) found that the children with ASD's level of social ability was not related to special education service use. This is concerning, given the deleterious effect of children with ASD's social deficits on their performance in the classroom setting (Thomeer et al. 2017), especially with the reported overarching suppression of social ability among children with ASD (White et al. 2007). Finally, the majority of students with ASD in special education received speech therapy, followed by physical and/or occupational therapies (White et al. 2007). Social skills instruction was much less frequently reported for children in the younger

elementary grades, with none of the parents of older children (grades 7 and 8) reporting that their children received this service. Given the potential benefits of social skills instruction in the schools (Thomeer et al. 2017), services that would directly ameliorate social deficits continue to be an area of unmet need (White et al. 2007).

Wei et al. (2014) examined three national datasets of functionally heterogeneous students with ASD for patterns of special education services use. Wei et al. (2014) found that students with ASD and higher levels of ASD symptoms were more likely to receive more special education services, and that service use generally declined with increasing age. In addition, they noted how educational priorities may shift as a student ages, with age moderating how the students experience special education services and supports. For elementary school students, the two most common therapies were speech and language therapy (84.6%), followed by occupational therapy (50.0%). In contrast, a relatively lower percentage of students received a behavior management program (43.8%), service coordination (39.5%), adaptive physical education (39.1%), learning strategies/study skills support (29.5%), or social work services (6.4%). Secondary school children with ASD also followed a similar pattern, with speech services being the most frequently accessed service for children with ASD in special education.

While these service usage results reported by Wei et al. (2014) are consistent with prior research (White et al. 2007), the authors also noted the discrepancy between the widespread social and behavioral impairments experienced by students with ASD and lack of social/behavioral services delivered in schools. Therefore, this represents an area of unmet need in the special education system (Wei et al. 2014; White et al. 2007). In addition, the low percentage of elementary school children with ASD accessing learning supports reported by Wei et al. (2014) further confirmed the assertion that these services are underemphasized in the IEPs developed for students with ASD (White et al. 2007). Finally, Wei et al. (2014) found that 3.4% of elementary/middle school and 6.7% of high school children with ASD did not receive

any of the three services (i.e., speech and language therapy, occupational therapy, behavior management program) thought to directly address ASD symptoms.

McDonald et al. (2019) examined the service use of a sample of 89 children (ages 6–11 years) diagnosed with ASD without ID. The children's IEPs were evaluated for special education classification, type of service received (e.g., speech therapy, occupational therapy, physical therapy, individualized behavior support plan, social skills instruction, counseling, and 1:1 aide), duration of service, and type of placement (i.e., full inclusion, partial inclusion, and self-contained classroom). For the purpose of their study, McDonald et al. (2019) defined full inclusion as the placement for a child who remained in the mainstream, general education setting for the entirety of the school day. Partial inclusion was defined as the placement for children who attended general education for the majority of their school day, but less than 100% of all subjects were taught in the general education setting. Students in this placement typically were removed from the general education setting briefly for more intensive instruction in a specific subject area, such as math and/or reading. Finally, a self-contained classroom was defined as the placement for children who primarily remained in this more restrictive special education classroom (with a smaller teacher-to-student ratio) and only were included into the general education setting for a maximum of two academic classes. McDonald et al. (2019) reported that partial inclusion was the most frequent placement (40%), followed by full inclusion (34%) and self-contained classroom settings (26%). Over half of the participants ($n = 50$, 56%) were classified under Autism, followed by OHI (27%). In addition, the researchers found that children classified under Autism were about twice as likely to receive 1:1 aide services as children with ASD who met other special education classifications. In regards to the whole sample, the most frequently provided services included speech therapy (71%) and occupational therapy (56%) in line with prior research (Wei et al. 2014; White et al. 2007). However, unlike past research, counseling services were the

third reported most frequent service (44%). This is noteworthy, as evidence for the use of cognitive-behavioral strategies with children with ASD without ID is increasing (Ho et al. 2018), although counseling has not been widely examined in the special education service use literature. In contrast with these top three services accessed, social skills instruction and behavior support plans were the least common (17% and 16%, respectively) services rendered.

Although not specifically examining counseling, in a rare study looking at mental health services in the schools, Narendorf et al. (2011) examined a sample of adolescents with ASD ($n = 920$), drawn from the National Longitudinal Transition Study-2 (NLTS2) who qualified for special education services via an educational classification of Autism. Of these youth, 49% of the sample reported using a mental health service in the past, with 47% of these youth accessing mental health services through the special education system in schools. Factors that increased the odds of accessing these services via the school system included being African American, or having a household income below \$50,000 (in comparison to families having a household income greater than \$70,000; Narendorf et al. 2011). Parent involvement in the IEP process, as well as child characteristics of displaying poor social skills, experiencing bullying, or perpetrating bullying were associated with accessing mental health services, but not associated with accessing these services in schools.

Future Directions

Research in the area of special education service use by children with ASD and its relationships with child and placement variables continues to be limited (McDonald et al. 2019; Wei et al. 2014; White et al. 2007). Further research is needed that examines what special education services children with ASD receive, as well as the amounts and types of special education services accessed and their relationship to the children's demographic variables (e.g., age, IQ, level of ASD symptoms,

communication ability, and other adaptive behaviors; Lauderdale-Littin et al. 2013; McDonald et al. 2019; White et al. 2007). Documenting special education service use by children with ASD is important as it may inform the training needed for school personnel who work with children with ASD (McDonald et al. 2019; Wei et al. 2014). In addition, the documentation of special education service use may be a resource used to inform families as to what special education services a child with ASD typically receives (or may need), and what they might be inclined to advocate for (McDonald et al. 2019; Wei et al. 2014). For example, Thomas et al. (2007) found that parents of children with ASD report that not only is speech therapy one of the most widely-used services in special education, but it is considered by many parents as one of the best services (followed by occupational therapy) their child receives in the school. While speech services are often necessary (especially given the documentation of lower communication skills in this population), it is essential to understand the child demographic and behavioral characteristics associated with special education placement and service use decisions (Lauderdale-Littin et al. 2013) and inform families, school personnel, and other stakeholders of these relationships. Given the disparities between level of social/behavior services provided in schools and the social/behavioral needs of children with ASD highlighted by multiple researchers (McDonald et al. 2019; White et al. 2007; Wei et al. 2014), families and school staff of students with ASD should advocate for appropriate social and behavioral interventions in schools. In addition, further examination of how children with ASD are or are not succeeding socially in the various special education placements is warranted (White et al. 2007). This research should also focus its investigation on the potential existence of a social benefit purported to be received from placement in the general education setting (White et al. 2007).

Future research also needs to focus on understanding the barriers to accessing special education services throughout students with ASD's school tenure (Wei et al. 2014). Most importantly,

more examination of the reasons behind the decline of speech and occupational therapies and behavioral services needs to be conducted, as this also indicates that accessing special education services may become more difficult as children with ASD age (Wei et al. 2014). In addition, barriers to minorities accessing special education services needs to be examined, as research has mixed results on the success these subgroups have had in receipt of services, which is typically below their Caucasian peers (Wei et al. 2014), aside from the propensity to access mental health care in the school setting at higher rates (Narendorf et al. 2011). Finally, further examination of the implementation of counseling and other mental health services in the schools should be studied, in order to gain more information as to the implementation of and access to these services across the various age ranges.

Definition

Special needs is a term often used to describe the needs of individuals with disabilities or who are at risk of developing disabilities and their unique needs as a result of deficits related to a disability or disorder, who require or may require in the future special services or treatment. Needs typically refer to special care, services, or accommodations necessary to support the individual or those supporting the individual with a disability or disorder. Special needs most often refer to intervention, curricula, behavior management, and transition planning; however, individual accommodations and modifications related to deficit of the disability are addressed under this term.

Special Needs Planning (SNP)

Annemarie M. Kelly and Christina N. Marsack-Topolewski
College of Health and Human Services, Eastern
Michigan University, Ypsilanti, MI, USA

Definition

Special needs planning (SNP) is a process of collecting, coordinating, and consolidating legal, financial, health, and personal wellness information concerning an individual with disabilities to ensure that the individual receives support in the future. SNP activities can help to improve an individual's quality of life and provide resources for goods and services that are not covered under government benefits programs or private health insurance plans. The overarching goal of SNP activities is to create a well-informed plan for an individual's future care and resources.

Principles of Special Needs Planning

SNP activities can assist individuals who have autism spectrum disorder (ASD) in making financial resources available to pay for current and future needs that are not covered by government

Special Needs Planning (SNP), Table 1 Examples of SNP benefits and instruments

Potential benefit	Examples of instruments that provide assistance
Ensuring funds are available to a beneficiary without jeopardizing eligibility for government benefits	Special needs trust (SNT) and Achieving a Better Life Experience account (ABLE or 529A account)
Ensuring assigned individuals available to assist the beneficiary as needed	Decision-making support agreement, guardianship, conservatorship, letter of intent (LOI), Power of Attorney for money and property, and Power of Attorney for healthcare
Ensuring that funds are well managed to meet the beneficiary's needs	Legal or financial agent agreement, decision-making support agreement, guardianship, and conservatorship
Document preferences for future transition-of-care planning to prepare for a time when a beneficiary's current caregivers can no longer provide care	Letter of intent (LOI), Power of Attorney for healthcare, and advance directive

benefits or private health insurance (Marsack-Topolewski and Church 2019; Thomas et al. 2016; Parish et al. 2015; Horlin et al. 2014; and Montes and Halterman 2008; see also Krakovich et al. (2016) and Cidav et al. 2012). The person who receives the benefit of SNP activities is often referred to as the “beneficiary.” SNP has the potential to offer multiple forms of assistance and security to a beneficiary. See Table 1, Examples of SNP benefits and instruments. The individual beneficiary should be involved in the planning process to the greatest extent possible (National Council on Disability 2018). Other individuals involved in the SNP process often include family members, friends, and legal guardians or conservators (Trentacosta et al. 2018).

There are three fundamental phases of SNP activities: (A) Identifying costs for essential needs; (B) Identifying costs for preferred goods and services; and (C) strategizing with guidance from legal and finance professionals. See Table 2, Twelve key steps in the SNP process. The initial steps involve confirming information about the beneficiary. Information collection for the SNP process is often conducted by a close caregiver of the beneficiary. First, the caregivers must document which short and long-term expenses are absolutely essential, and which are merely desirable. The time spent collecting detailed information about the beneficiary's desires and needs will allow legal and financial planners to offer personalized guidance for SNP strategies (Russell and Grant 2010). With clearly organized information about an individual with disabilities' unique

circumstances, professional advisors are better able to provide well-informed SNP guidance.

To gather the necessary information for SNP, individuals with disabilities and/or their caregivers should outline short- and long-term goals for the beneficiary's living, healthcare, wellness, educational, vocational, and emergency needs (Tencza and Forsythe 2019; Lauderdale and Huston 2012). As a next step, the beneficiary or caregiver must create a list of all of the goods and services that are necessary to meet the beneficiary's goals. Each item on the special needs planning list should correlate to an “out of pocket” cost – a good/service that is not covered under the beneficiary's government benefits programs and/or private health insurance. Individuals who are working to collect details to inform a special needs plan must consider that SNP information comes from a variety of sources that include many professional disciplines. One of the preferred means to create a thorough, well-informed summary of the beneficiary's needs is to seek information about the beneficiary's needs from multi-disciplinary groups of experts, particularly those in health and human services fields. See Table 3, Health and human services professionals who may assist during the SNP information collection phase.

Many technical SNP services are performed by an experienced attorney, financial planner, and/or tax advisor (see generally, American Bar Association Diversity and Inclusion Center Commission on Disability Rights Resources 2019). Though many for-profit and non-profit businesses offer

Special Needs Planning (SNP), Table 2 Twelve key steps in the SNP process

A. Identify costs for essential needs not covered by government programs and private health insurance	
Step 1	What are the beneficiary’s short- and long-term goals in the following areas: healthcare, personal wellness, education, and vocation?
Step 2	Which essential goods or services are required for the beneficiary to satisfy the goals identified in Step 1?
Step 3	Which of the goods or services identified in Step 2 are not covered by government benefits programs and/or private health insurance?
Step 4	What are the out-of-pocket costs for goods or services identified in Step 3 (per item/session, monthly, and annually)?
Step 5	Of the goods and services identified in Step 4, which are needed for a limited amount of time and which are permanently needed? Can any of the beneficiary’s healthcare providers provide additional information to help answer this question?
B. Identify costs for preferred goods and services not covered by government programs and private health insurance	
Step 6	Considering the goals identified in Step 1, which goods or services are desirable/preferred for the beneficiary?
Step 7	Which of the goods or services identified in Step 6 are not covered by government benefits programs and/or private health insurance?
Step 8	What is the out-of-pocket cost for goods or services identified in Step 7 (per item/session, monthly, and annually)?
Step 9	Of the goods and services identified in Step 7, which are needed for a limited amount of time and which are permanently needed? Can any of the beneficiary’s healthcare providers provide additional information to help answer this question?
C. Strategize with guidance from legal and finance professionals	
Step 10	Which attorney can best assist in writing and implementing the legal instruments for the special needs plan that is based on the information collected in in Steps 1–9? What is the attorney’s guidance on how to budget for emergency expenses in addition to the goods and services identified in Steps 1–9?
Step 11	Which financial planner can best assist in analyzing wealth management and tax reporting strategies to maximize the funds for the special needs plan?
Step 12	Review the special needs plan annually and update it to reflect any changes in the beneficiary’s needs and circumstances.

generalized SNP forms online, it is a strongly recommended best practice to retain an attorney to write and implement legal instruments that are tailored to the beneficiary’s unique needs. Legal instruments for SNP include, but are not limited to: special needs trusts (SNTs), Achieving a Better Life Experience accounts (ABLE or 529A accounts), Last Will and Testament documents, guardianships, conservatorships, letters of intent (LOIs), Power of Attorney for money and property; Power of Attorney for healthcare; money management services; and supported decision-maker agreements (Andersen and Gary 2018). Because a beneficiary’s preferences, health, and financial circumstances can change over time, it is a recommended best practice for caregivers to review a beneficiary’s special needs plan annually and to work with legal and financial advisors to make updates as needed.

In the United States, the SNP process should not be confused with the term “Medicare Special Needs Plans (“Medicare Advantage”), which are tailored health coverage plans that assist people with specific health conditions in accessing provider specialists, particularly drug formularies, and other unique benefits.

Common Barriers to Special Needs Planning

Over the past several years, multiple qualitative studies have found that a significant proportion of individuals with disabilities and their families are unready or unwilling to make future plans (Walker and Hutchinson 2018). Burke et al. (2018) summarize this concern as follows:

Special Needs Planning (SNP), Table 3 Health and human services professionals who may assist during the SNP information collection phase

Aging studies expert
Art therapist
Music therapist
Nurse practitioner, registered nurse, and/or home health nurse
Occupational therapy (OT) practitioner
Physiatrist
Physical therapy (PT) practitioner
Physician's assistant
Primary physician
Psychologist
Recreational therapist
Registered dietitian
Social worker
Special education expert
Speech pathologist

Special Needs Planning (SNP), Table 4 Commonly cited reasons why individuals do not engage in effective SNP

Lack of available services
Financial challenges
Reluctance of family members
Lack of time
The emotional nature of future planning
Inertia and/or disinterest in SNP issues
Lack of family members to be caregivers
Perceived lack of need due to the existence of current caregivers
Lack of awareness and understanding about SNP processes
Lack of confidence in available housing options
Lack of confidence in available options for retaining SNP professionals
Existence of mutually supportive relationships
Opinion that the beneficiary does not require any goods or services that are not covered by public benefits programs

Although many families want to engage in future planning, families often treat future planning as more aspirational than definitive. . .Parents often do not create actual plans; however, when parents create plans, their wishes for their offspring are more likely to be fulfilled.

Researchers report numerous barriers to future planning using SNP tools (Burke et al. 2018; and Bowey and McGlaughlin 2007). See Table 4, commonly cited reasons why individuals do not engage in effective SNP. Walker and Hutchinson (2019) have identified three overarching themes that arise in SNP scenarios: (1) external barriers to planning involving reservations about available services; (2) internal barriers within family and caregiver groups that prevent planning (e.g., mutual dependency and sense of helplessness); and (3) existence of diverse ideas and misconceptions about planning and ways of managing the future. Though a range of external and internal factors pose as barriers to SNP processes, a growing body of evidences suggests positive outcomes for individual beneficiaries and families once they engage in a future planning process (Brennan et al. 2020; Weiss et al. 2014; Heller and Kramer 2009).

Special Needs Trust (SNT)

Annemarie M. Kelly and Christina N. Marsack-Topolewski
College of Health and Human Services, Eastern Michigan University, Ypsilanti, MI, USA

Definition

A special needs trust (SNT) is a legal instrument established to hold money or property for the benefit of a person with disabilities. The recipient

of SNT assets is commonly referred to as a “beneficiary.” An SNT allows a benefactor, often called a “grantor,” to give money or property to a beneficiary without disrupting the beneficiary’s eligibility for government benefit programs (U.S. Social Security Administration 2020a). Assets that are held in an SNT account for a beneficiary are managed by a trustee. Generally, SNT holdings are not considered as a source of income to a beneficiary. Specific legal requirements for creating, administering, and funding an SNT are set forth in federal statutes, state statutes, and administrative regulations from federal and state agencies (e.g., the Social Security Administration (SSA), Centers for Medicare and Medicaid Services (CMS), and Internal Revenue Service (IRS)).

Principles of Special Needs Trusts

An SNT can be a useful special needs planning tool for individuals with autism spectrum disorder (ASD) and their caregivers to manage financial resources. When properly designed and administered in accordance with legal requirements, SNTs help people with disabilities to receive financial resources for their benefit while also qualifying to receive assistance from government programs like Medicare, Medicaid, and Social Security Incomes (SSI). For this reason, SNTs are sometimes referred to as “supplemental needs trusts.”

Individuals with disabilities cannot receive benefits through Medicaid and other government programs if they own significant financial resources that are not sheltered in an SNT or other special needs planning instrument. SNT legal doctrine considers state and federal government benefits as essential healthcare resources for individuals with disabilities. As a whole, SNT laws safeguard qualified individuals’ access to government benefits so that people can access comprehensive support networks and receive the care that they need. Many people with complex healthcare requirements rely on goods and services from government benefits to complete their activities of daily living (“ADLs” or basic self-care tasks) and instrumental activities of daily

living (“IADLs” or tasks to organize, manage, and interact with one’s environment). An SNT is sometimes employed in instances where an individual has an influx of financial resources and wishes to maintain government benefits (e.g., *Lewis v. Alexander*, 685 F.3d 325, 332 (3d Cir. 2012)). Eligibility for state and federal government program benefits is based on Modified Adjusted Gross Income (MAGI). Assets held in SNTs for a beneficiary do not typically count toward the government’s MAGI calculations (U.S. Centers for Medicare & Medicaid Services 2020a). Before the creation of SNT laws, individuals with disabilities were forced to forego financial gains that placed them above the legal threshold for personal income so that they could retain their access to government benefits.

Expenditures from an SNT are often used to pay for a range of goods and services for the beneficiary that are not covered by public benefits, including certain caregiving and personal wellness costs. Allowances from an SNT can help a beneficiary to pay for short- and long-term costs that enhance his or her quality of life (Jackins et al. 2019). As a general rule in most jurisdictions, SNT funds can only be used for the special and supplemental needs of a person with disabilities, and not their day-to-day living expenses such as food and shelter (e.g., New York Consolidated Laws Estates, Powers and Trusts Law § 7-1.12 (2020)). Because certain types of purchases cannot be made from SNT funds under state and federal laws, a trustee must ensure that all spending from an SNT satisfies all applicable legal requirements.

Individuals who are interested in using an SNT should take care not to confuse an SNT document with a Last Will and Testament, sometimes called a “legal Will” (Andersen and Gary 2018). Both are legal documents that can convey money and property to a loved one; however, they differ in several respects (Wick 2019). In certain cases, if a grantor leaves his or her assets directly to a beneficiary through a Will and without an SNT or other special needs planning tool, the Will’s bequest could render the beneficiary ineligible for government sponsored-benefits. Assets in a Will are governed by probate law processes. All distributions from a Will must be reviewed by a probate

court judge to confirm that the Will is valid and any bequests were not induced by fraud. Because they move through the court system, any asset distribution to a beneficiary in a Will becomes part of public record (Feder and Sitkoff 2016). As a general rule, a properly constructed SNT is not subject to the probate process and will not be deemed as income that could jeopardize the beneficiary’s eligibility for government benefits.

Creation of Special Needs Trusts

Three key parties are required to create an SNT: (1) grantor (the provider of trust assets and often parents, family members, or friends of the trust beneficiary), (2) trustee (the manager of trust assets), and (3) beneficiary (recipient of trust assets) (Table 1). The terms of an SNT are confirmed in a trust document, which constitutes a binding legal contract between a grantor and trustee (Wilcenski and Pleat 2020, April). As a

recommended best practice, an SNT document should always be written by a qualified attorney. Ideally, grantors and beneficiaries (including beneficiary guardians and conservators) should analyze specific legal, investment, and tax strategies in detail with both a tax advisor/financial planner and their special needs planning attorney (Lauderdale and Huston 2012).

Though several non-profit and for-profit organizations offer generalized forms for SNTs online, experts highly recommend obtaining personalized advice from experienced legal and financial professionals who can best tailor the SNT and other special needs planning tools to address particular needs and circumstances. As Hickman-Ladd (2019) explains,

Clients with special needs or a client’s family member with special needs can range from a child to an older adult. The planning will differ from client to client and depend on where each individual with special needs is in his or her life. Therefore, an attorney will consider different planning tools for each client.

Special Needs Trust (SNT), Table 1 Three key parties involved in an SNT

Party name	Description	Overview
Grantor	Provider of trust assets (money or property)	Grantors are often parents, family members, or friends of the trust beneficiary
		A grantor formally appoints a trustee for the SNT in a trust document
		By signing a trust document, grantors specify exactly how they would like the trustee to manage the SNT assets
		A signed trust document also specifies a grantor’s wishes regarding when the SNT assets should be distributed to the beneficiary – an SNT can be designed to take effect during the grantor’s lifetime or upon the grantor’s death
Trustee	Manager of assets	Trustees have a legal duty to manage the SNT for the benefit of the beneficiary
		A trustee must avoid conflicts of interest between his or her personal finances and the beneficiary’s finances
		Because a host of distributions from an SNT are not permitted by state or federal law, trustees must ensure that all SNT expenditures are in accordance with legal requirements
		A trustee can be a specific individual or an organization such as a bank or other financial institution
Beneficiary	Recipient of assets	A beneficiary can receive funds from an SNT without losing his or her eligibility for government-sponsored benefits
		Depending on the wording of the trust document, a beneficiary can receive payments from an SNT immediately after the trust is created or be entitled to funds sometime in the future (e.g., upon the death of the grantor, the beneficiary’s 21st birthday, or other specified date)

Because SNT laws are complex and situation specific, grantors and beneficiaries who engage in “Do-It-Yourself” SNT planning may render themselves liable for tax penalty fees for accidental noncompliance with federal and state requirements. By retaining professional assistance, SNT parties are more likely to avoid legal mistakes and see that their needs are comprehensively addressed. Moreover, professional guidance can help to ensure all short- and long-term goals for the beneficiary’s SNT finances account align with wills, guardianships/conservatorships, and other legal instruments that are specific to the beneficiary’s circumstances.

Types of Special Needs Trusts

There are varying legal requirements for grantors, beneficiaries, and trustees under federal and state laws. Technical legal requirements concerning SNTs include how assets must be executed, funded, managed, allocated after a beneficiary’s

death, and reported to the U.S. Internal Revenue Service (IRS) for tax and income purposes (U.S. Internal Revenue Service 2020). The particular rules that apply in a given situation depend largely on the type of SNT that is created by the grantor and trustee for the beneficiary (Russell and Grant 2010).

In the USA, there are three primary categories of SNT: self-funded trusts, third-party trusts, and pooled trusts (Table 2). Each type of SNT can be designed to hold assets without making the beneficiary ineligible for needs-based public benefits (U.S. Social Security Administration 2020b). SNT terminology sometimes varies among state jurisdictions and individual preferences. The terms “SNT” and “supplemental needs trusts” are often used interchangeably (Wilcenski and Pleat 2016). Nevertheless, individuals who are analyzing SNT issues should be aware that some state laws use the term “SNT” to refer only to self-funded and pooled trusts and define “supplemental needs trust” as solely third-party trusts (Table 3).

Special Needs Trust (SNT), Table 2 Three primary types of SNTs

Special needs trust type	Summary	Occurrences after a beneficiary’s death	Key federal statutes and social security administration regulations
Self-funded trust	SNT funded with the beneficiary’s own assets. Funds may include, but are not limited to: the beneficiary’s income from employment, inheritance, or a personal injury lawsuit settlement. This SNT can only be established for beneficiaries under age of 65	Any remaining assets may be subject to Medicaid Estate Recovery (payment collection by the government)	42 U.S.C. § 1396p(d)(4)(A); POMS SI 01120.200(B)(4)
Third-party trust	SNT established by a third-party and funded entirely with third-party assets. The beneficiary’s own assets cannot be used to fund this trust	Any remaining assets are freely transferable by the grantor (and not subject to Medicaid Estate Recovery)	42 U.S.C. § 1396p(d)(2)(A)(iii)–(iv); POMS SI 01120.200(B)(16)
Pooled trust	SNT created and administered by a nonprofit entity that creates individual trust for the beneficiary to use during his or her lifetime. A pooled trust contains the assets of several different individuals that are maintained in separate accounts for each beneficiary. Account funds are pooled together for investment purposes. This SNT can be established for an individual with disabilities any age	Depending on state law, some or all of the assets remaining in a pooled trust account may revert to the other remaining beneficiaries or be kept by the charity trustee. In cases of first-party pooled trusts, any remaining assets may be subject to Medicaid Estate Recovery. In cases of third-party pooled trusts, any remaining assets are freely transferable by the grantor	42 U.S.C. § 1396p(d)(4)(C); POMS SI 01120.200(B)(9)

Special Needs Trust (SNT), Table 3 Common terminology differences among SNT types

Self-funded trust	Pooled trust	Third-party trust
First-party trust	Pooled income trust	Supplementary trust
OBRA-93 trust, OBRA’ 93 trust, or OBRA trust	OBRA-93 trust, OBRA’ 93 trust or OBRA trust	Pooled supplemental needs trust
d4A trust	d4C trust	Third-party pooled trust
Grantor trust	First-party pooled trust	Self-funded payback pooled trust
Self-settled special needs trusts	Third-party pooled trust	
Self-funded payback trust	Pooled supplemental needs trust	
Medicaid payback trust	Pooled Medicaid payback trust	

As its name suggests, a self-funded SNT (also known as a “first-party SNT,” “OBRA-93 trust,” or “d4A trust”) is financed with a beneficiary’s own assets (42 U.S.C. § 1396p(d)(4)(A) (2020)). Funds for a self-funded SNT may include, but are not limited to, funds from an inheritance, retirement plan, divorce settlement, life insurance policy, or personal injury lawsuit settlement. Under certain conditions, any assets that remain in a self-funded SNT after a Medicaid enrollee has passed away may be used to reimburse the government for Medicaid benefits provided to the beneficiary during his or her lifetime. This process is often called “Medicaid Estate Recovery” (U.S. Centers for Medicare and Medicaid Services 2020b). Under federal law, states may not recover from the estate of a deceased Medicaid enrollee who is survived by a spouse, child under age 21, or a child of any age who is blind or has a serious disability (42 U.S. Code § 1396p (2020)).

In cases of pooled SNTs, a non-profit agency serves as the trustee and maintains a separate account for multiple individual beneficiaries (42 U.S.C. § 1396p(d)(4)(C) (2020)). This type of trust maintains one large account and individual beneficiaries have sub-trust accounts. With each individual trust account in one group, a single trustee or group of trustees can streamline investment and management tasks for the collective SNT pool. Weikel (2018) discusses the efficiencies of pooled trusts stating,

The benefit of a pooled trust is that the sub-trust accounts are pooled together for investment and management purposes, making the cost of

administration low (depending upon the choice of non-profit trustee). Furthermore, pooled trusts comprise professional trustees armed with more sophisticated knowledge of the complexities of SNT administration than the average family member of a disabled beneficiary serving as trustee.

Depending on which state law applies in a given situation, some or all of the assets remaining in the individual’s trust may revert to the other remaining beneficiaries or be kept by the charity trustee after one pooled trust beneficiary dies.

Third-party SNTs require a third-party donor to contribute the assets for the benefit of someone else (i.e., not for themselves) (42 U.S.C. § 1396p (d)(2)(A)(iii)–(iv) (2020)). Typically, if a balance remains in this trust upon the beneficiary’s death, the remaining assets are freely transferable by the grantor and not subject to estate recovery. Third-party SNTs can be included in the grantor’s Will. If an SNT is created through a Will, the trust will not activate and allow the beneficiary to access trust funds until after the grantor’s death. In cases where multiple donors wish to fund an SNT, it is preferable to create an SNT that is independent of a Will.

Key Considerations for Grantors When Creating a Special Needs Trust

During the process of creating a trust, grantors must consider seven primary issues: (1) Which assets (cash, stocks, bonds, real estate, and other property of value) will I put into the trust?;

(2) Who will receive the assets as the trust’s beneficiary?; (3) What is the name of the individual or organization that will manage the assets as the trustee? (Wilcenski and Pleat 2019, March); (4) What are the stipulations for this trust – i.e., should the trust funds be available immediately for the beneficiary or become eligible for withdrawal at a later date? (e.g., Sullivan 2010); (5) In the event I can no longer oversee the trustee’s actions because of a serious disability or injury, should my grantor responsibilities for this SNT refer to my named Power of Attorney?; (6) Can I structure this SNT to coordinate with the beneficiary’s Achieving a Better Life Experience (“ABLE” or “529A”) account?; and (7) Which special needs planning attorney and financial professional can best assist me in creating and implementing this SNT? (Table 4).

In many cases, an SNT is most advantageous for a beneficiary when combined with other special needs planning tools as part of a comprehensive long- and short-term budget plan (Rephan and Groshek 2016) (Table 5). For example, if an SNT beneficiary has an ABLE account, Hershey and Kelly (2019) recommend coordinating the use of relatively lower amounts in an ABLE account in tandem with greater savings in a third-party SNT. In this scenario, the ABLE account should be spent down entirely before the beneficiary’s death to avoid a loss of funds in the Medicaid Estate Recovery process. Funds remaining in the SNT can be freely transferred to another person or charity organization after the beneficiary’s passing (Hershey et al. 2015). All in all, a special needs planning attorney can help to ensure that the terms of a trust document are written correctly to meet the grantor’s goals.

Special Needs Trust (SNT), Table 4 Seven key considerations for grantors when creating an SNT

Issue	Key questions to consider
Type of trust	Which SNT type will best assist the beneficiary? What are the potential challenges and benefits associated with this type?
Content of the trust	Which assets will I put into the trust (e.g., cash, stocks, bonds, real estate, and other property of value)?
Trust funds recipient (beneficiary)	Who will receive the assets as the trust’s beneficiary? How will the SNT assets assist the beneficiary? How can I structure this SNT to best satisfy the beneficiary’s short- and long-term financial needs?
Trust funds manager (trustee)	What is the name of the individual or organization that will manage the assets as the trustee? Can the trustee objectively administer the trust in the best interest of the beneficiary and adhere to the terms of the trust contract?
Contract terms within the trust document (your ideas should be written by a special needs planning attorney using precise legal terms in the trust document)	What are the stipulations for this trust? Which type of SNT should I create? Should the trust funds be available immediately for the beneficiary or become eligible for withdrawal at a later date? How often should trust payments to the beneficiary occur – i.e., monthly installments, annual deposits to the beneficiary’s checking, or Achieving a Better Life Experience (“ABLE” or “529A”) account?
Future plans for the trust with grantor’s Power of Attorney	In the event I can no longer oversee the trustee’s actions because of a serious disability or injury, should my grantor responsibilities for this SNT refer to my named Power of Attorney? Is my Power of Attorney document up to date?
Hiring a special needs planning attorney and financial professional	Which special needs planning attorney and financial professional can best assist me in creating and implementing this SNT?

Special Needs Trust (SNT), Table 5 Comparing Achieving a Better Life Experience (ABLE) accounts and SNTs

Key considerations	Self-funded trust	Third-party trust	Pooled trust	ABLE account
What does the setup process include?	Attorney writes the trust document	Attorney writes the trust document	Grantor typically uses the non-profit organization's trust format, however, the language should also be reviewed by a special needs planning attorney	Each state offers online enrollment for beneficiaries (or their legal guardians) to create an account. State ABLE account programs encourage users to set up their own accounts, but also warn of the need for legal advice from an attorney and financial planner/tax advisor.
Is an attorney often used for the setup?	Yes, to ensure all trust terms are properly written and the grantor's wishes are satisfied	Yes, to ensure all trust terms are properly written and the grantor's wishes are satisfied	Yes, to ensure all trust terms are properly written and the grantor's wishes are satisfied	Though state ABLE account programs encourage do-it-yourself setup, personalized guidance from an attorney and financial planner/tax advisor is strongly recommended
If there is a balance remaining after beneficiary's death, are the assets subject to government payback (Medicaid estate recovery)?	Yes	No	Yes or no, depending on the structure of the trust and state law	Yes
Yearly fees	Yes, typically trustee and/or investment advisor fees	Yes, typically trustee and/or investment advisor fees	Yes, typically trustee and/or investment advisor fees	Yes, account maintenance fees (depending on the beneficiary's investment selections and the state ABLE program's administrative rules)
Yearly contribution limits	No	No	No	Yes, subject to the federal gift tax limit
Maximum contribution limits	No	No	No	Yes (the total amount varies between state ABLE program jurisdictions)

Legislative History of Special Needs Trusts

In 1993, the Omnibus Budget Reconciliation Act (OBRA) created many of the foundations

of current SNT law (Pub. L. No. 103–66 1993). OBRA confirmed that people with a disability to have a right to use an SNT to supplement their government benefits without jeopardizing their eligibility for means-tested

government benefits. Under the original wording of the OBRA law, a self-funded SNT could only be established by the SNT beneficiary's parent, grandparent, or guardian, or by a court.

In 2016, the 21st Century Cures Act amended federal law to expand regulations for creating self-funded SNTs (Pub. Law 114–255 2016). Under this law, individuals with a disability who have legal capacity can establish and make deposits into their own SNT savings accounts (excluding third-party SNTs). A beneficiary's legal capacity to create an SNT must be distinguished from his or her mental ability (Dudley and Edmonds 2018). Legal capacity embodies three pillars of individual legal rights: to have standing to bring and defend lawsuits; to enter into/execute legally binding contracts; and to appreciate the basic challenges and risks involved with an SNT (e.g., legal compliance and income tax reporting requirements). A legal milestone for disability rights, the Cures Act empowers individuals with disabilities who wish to save their own money using an SNT.

Special Olympics

Timothy Shriver

Special Olympics, Inc, Washington, DC, USA

Major Areas or Mission Statement

With sports at the core, Special Olympics stands as a leader in advancing rights, opportunities, and social change for people with intellectual disabilities around the world. In 2011, Special Olympics served nearly four million athletes worldwide. While the majority of the athletes (64.8%) are school-aged (8–21 years old), 33.4% are adults (22+), and 1.8% are young children (2–7), with more males (62%) than females (38%) participating. Special Olympics has been growing rapidly; since 2000, the Special Olympics athlete count has grown from just under one million to the current total of just under million.

Most staff in Special Olympics programs globally are volunteers with a wide variety of expertise, including credentialed sports coaches, health professionals, program administrators, and researchers. In 2011, more than 306,000 coaches supported Special Olympics athletes. In addition, 546,000 partners, or participants without disabilities, are now engaged in Unified Sports, a Special Olympics initiative that includes individuals with and without intellectual disabilities together. Nearly 29,000 of our athletes serve in leadership

positions offered through another initiative, the Athlete Leadership Programs (ALPs).

Because of its inclusive nature, Special Olympics does not collect disability-specific information on its athletes, and, as such, there is no nationwide data on the number of participants in Special Olympics who have autism spectrum disorder (ASD). However, studies suggest that between 6% (Weiss et al. 2003) and 19% (Glidden et al. 2011) of Special Olympics athletes have ASD.

Mission Statement

"The mission of Special Olympics is to provide year-round sports training and athletic competition in a variety of Olympic-type sports for children and adults with intellectual disabilities, giving them continuing opportunities to develop physical fitness, demonstrate courage, experience joy and participate in a sharing of gifts, skills and friendship with their families, other Special Olympics athletes and the community."

Landmark Contributions

Brief History

In 1962, Eunice Kennedy Shriver started a summer day camp for children and adults with intellectual disabilities in her backyard in Maryland. She hoped to not only provide this underserved population with access to recreational opportunities but also to explore their capabilities in a variety of sports and physical activities. Just 6 years later, this small summer camp grew into the First International Special Olympics Summer Games, held at Soldier Field in Chicago, Illinois, USA. Over 1,000 individuals with intellectual disabilities came from 26 U.S. states and Canada to compete in track and field and swimming.

As the movement grew, so too did its national and international recognition as a serious sports movement. In 1971, the U.S. Olympic Committee gave Special Olympics official approval to use the name "Olympics" in the United States, making Special Olympics one of only two organizations authorized to do so. Fifteen years later, the United Nations proclaimed the International Year of

Special Olympics (1986) under the banner "Special Olympics – Uniting the World," and just 2 years later, the International Olympic Committee (IOC) officially endorsed and recognized Special Olympics (1988). The backyard camp had grown into an internationally recognized organization.

The subsequent decades were dedicated to expanding existing Special Olympics activities, as well as implementing new initiatives, such as Unified Sports, which creates an inclusive sports experience for participants with and without disabilities; Healthy Athletes, which provides free health screenings for athletes; and the Global Messenger Program, which offers public speaking and presentation skills training to athletes who are interested in representing the movement internationally. The organization also expanded to include cutting-edge research and evaluation, including the "Multinational Study of Attitudes toward Individuals with Intellectual Disabilities" (Siperstein et al. 2003), the most comprehensive study ever conducted on the subject. When Special Olympics celebrated its 40th anniversary in 2008, it had grown to serve three million athletes in 173 countries around the world. Today, the organization stands as an international leader in research and advocacy for persons with intellectual disabilities. In fact, in 2010, the first Special Olympics Global Congress was held in Marrakech, Morocco, bringing together hundreds of movement leaders from countries around the world to chart the next 5 years of work.

Special Olympics is currently led by:

- Timothy P. Shriver, Ph.D., Chairman and Chief Executive Officer
- J. Brady Lum, President and Chief Operating Officer

Major contributions:

1. Special Olympics has shown that people with disabilities can participate in and benefit from sports and recreation. The movement has demonstrated that the same motivation, desire, and ability to play and compete are present in people, irrespective of the presence of a disability.

2. Special Olympics has documented the developmental significance of sports and recreation across the lifespan for people with disabilities, from motor skill development in young children ages 2–7 to community engagement for adults.
 3. Special Olympics has led a movement of community inclusion by engaging millions of volunteers in meaningful experiences with people with intellectual disabilities, while also creating inclusive sports activities.
 4. Special Olympics has acted as a public education and attitude change vehicle, presenting people with intellectual and developmental disabilities in valued and respected social and community roles all around the world.
 5. Special Olympics has globalized the notion of sports and recreation for people with ID, particularly in developing countries.
 6. Special Olympics has demonstrated its ability to change attitudes – challenging and eliminating the stigma associated with intellectual or developmental disabilities – and instead highlighting the value of and skills possessed by people with ID, inspiring people to become advocates for inclusive education, employment, health care, and public policy.
 7. Special Olympics has pushed the boundaries of scholarly inquiry into the methods and models of personal and social change for people with intellectual disabilities.
 8. Special Olympics has launched a worldwide movement to combat health disparities and discrimination in health-care systems and the largest public health system has established Healthy Athletes, for people with ID in the world.
- Unified Sports: Unified Sports brings together equal numbers of Special Olympics athletes (with intellectual disabilities) and unified partners (peers without disabilities) on sports teams for organized, structured training and competition against other unified teams.
 - Healthy Athletes: Healthy Athletes offers free health screenings and health information to athletes and families at local, regional, and world games.
 - Young Athletes: Young Athletes is a curriculum designed to promote motor and social development for children ages 2½ to 7 through motor play activities and games.
 - Motor Activity Training Program: The Motor Activity Training Program is designed to provide individualized training programs for athletes with severe or profound intellectual disability who are unable to participate in official Special Olympics sports competitions because of their skill and/or functional capabilities.
 - Get Into It: The Get Into It educational resources explore the subjects of inclusion, acceptance, and social justice through the lens of core curriculum requirements and a service-learning framework.
 - Project UNIFY: Project UNIFY is a school-based initiative that uses sports and education programs to activate young people to develop school communities where all youth are agents of change – fostering respect, dignity, and advocacy for people with intellectual disabilities.
 - Athlete Leadership Programs (ALPs): The Athlete Leadership Program allows athletes to explore opportunities for greater participation in Special Olympics beyond sports training and competition as coaches, officials, team captains, spokespeople, and Board and committee members.
 - Research and Policy: Special Olympics conducts cutting-edge research and evaluation to better understand the many challenges faced by people with intellectual disabilities and the impact of Special Olympics on their lives. This research is also a driving force for realizing improved policies, laws, and rights for

Major Activities

Overview of Special Olympics programs:

- Sports Training and Competition: Special Olympics offers a variety of sports training and competitions for people with intellectual disabilities. In 2011, over 53,000 competitions were organized around the world, resulting in an average of 146 competitions every day.

people with intellectual disabilities around the world.

- **Special Olympics Family Support Network:** Family members of a person with intellectual disability often feel confused and alone. Special Olympics Family Support Network provides them acceptance, resources, hope, and a chance to become advocates – making them a valued voice in our movement.
- **Special Olympics Camp Shriver:** A camp experience for people with intellectual disabilities to learn new sports skills, participate in individual and team sports, and build friendships. The camp creates an atmosphere of understanding, learning, and sharing so that new friendships between athletes and participants without intellectual disabilities (partners) are created and continue to thrive once camp is over.

The Value of Special Olympics

There is growing empirical evidence demonstrating the value of Special Olympics for its participants, both with and without disabilities. Studies have shown that Special Olympics athletes gain not only improved sports skills but also improved physical fitness (Balic et al. 2000), increased self-esteem (Castagno 2001), increased self-perceptions of physical competence and social acceptance (Weiss et al. 2003), and improved social competence (Dykens and Cohen 1996). Indeed, athletes and families typically choose to participate in Special Olympics not only because of its sports opportunities but also because it is fun and offers prospects for social interaction (Harada and Siperstein 2008; Harada et al. 2011). There is also evidence that participation in Special Olympics decreases problem behaviors (Rosegard et al. 2001) and increases adaptive behaviors (Favazza and Siperstein *in press*; Favazza et al. *under review*). Further, typically developing individuals who participate in Unified Sports alongside teammates with intellectual disabilities have also demonstrated higher self-esteem, as well as greater willingness to interact with and more positive perceptions of individuals with disabilities (Castagno 2001). In addition, parents of Special

Olympics athletes frequently find that participation in Special Olympics raises their expectations of their son or daughter's abilities (Glidden et al. 2011; Kersh and Siperstein *under review*).

Although the benefits of participation in sports and recreation – and particularly in Special Olympics – have been well established for individuals with intellectual disabilities, only recently has the field begun to recognize the potential impact of sports and recreation on the social and motor development of individuals with autism spectrum disorder (ASD). Children with ASD frequently demonstrate motor impairments (Getchell and Lynch 2007), may be less physically active than their typically developing counterparts (Pan 2008), and are less involved in social and recreational activities with peers than those without disabilities (Solish et al. 2010). However, in their recent review of research on exercise and persons with ASD, Lang et al. (2010) found that persons with ASD participating in regular exercise experienced reductions in stereotypic, aggressive, and off-task behaviors. In addition, studies have suggested that participation in physical activity and recreational programs may have positive social benefits for individuals with autism, such as improved social behavior (Pan 2010) and increased social interaction (Garcia-Villamizar and Dattilo 2010), in addition to personal benefits, such as decreased stress and improved quality of life (Garcia-Villamizar & Dattilo). Of course, given the variability in specific deficits associated with ASD, some individuals may struggle with certain elements of team sports, including verbal and nonverbal communication with peers, loud noises, or personal contact (Crollick et al. 2006). Therefore, to maximize the benefits of sports and recreations, some adaptations – such as visual supports to present clear and predictable expectations (Fittipaldi-Wert and Mowling 2009), smooth transitions between activities (Crollick et al. 2006), and reinforcement of appropriate social and physical behaviors (Reid et al. 2003) – are often necessary.

The inclusive nature of Special Olympics requires that athletes not be singled out on the basis of their specific disabilities, and as a result,

Special Olympics does not have distribution numbers by specific intellectual/developmental disability subcategories. However, there is burgeoning preliminary evidence that individuals with ASD have participated in and enjoyed Unified Sports, inclusive summer camps (Special Olympics Camp Shriver), and traditional Special Olympics competitions. Additionally, families have spoken of a number of benefits of Special Olympics for their child with ASD, particularly in improved social skills and increased opportunities for social interaction (Kersh and Siperstein [under review](#)). Moving forward, Special Olympics will focus on how to best adapt its array of activities in order to accommodate its growing number of participants with ASD.

Spectrum/Continuum of Autism

Somer Bishop

Department of Psychiatry, University of California, San Francisco, CA, USA

Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

Definition

Autism is one of a spectrum of disorders that includes Asperger syndrome, pervasive developmental disorder-not otherwise specified (PDD-NOS), childhood disintegrative disorder (CDD), and Rett's disorder. These disorders are currently classified under the umbrella term of "pervasive developmental disorder (PDD)" in both the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV; American Psychiatric Association [APA] 1994) and the International Classification of Diseases (ICD-10; World Health Organization [WHO] 1992), but the term "autism spectrum disorder (ASD)" (also sometimes called autism spectrum condition (ASC)) is now more commonly used. Given the current state of knowledge, ASD appears to be a more useful description than PDD. It identifies autism as the reference point and suggests that at least some of the other disorders classified as PDD (i.e., atypical autism, PDD-NOS, Asperger syndrome) are differentiated from autism primarily by the age of onset, severity of symptoms, and presence of language delay and/or intellectual disability, whereas they are differentiated from non-spectrum disorders on the basis of several qualitative (and presumably biological) variables. Although CDD and Rett's disorder are also currently included in the PDD/ASD category, both of these disorders are exceedingly rare and differ significantly from other ASDs in the pattern of onset. In addition, given that there is now an identified genetic cause for the majority of cases of Rett's syndrome (Amir et al. 1999), it is unlikely that this disorder will be

included in the ASD category in DSM-V. Thus, the following discussion focuses on autism, PDD-NOS, and Asperger syndrome, referred to collectively as ASD.

Historical Background

Individuals with ASD present with diverse sets of symptoms and behaviors that vary as a function of many different factors, including age, language, IQ, and severity of social/communication symptoms and restricted and repetitive behaviors. The concept of a spectrum is therefore useful because it suggests that two individuals “on the spectrum” may look very different from one another even though they are classified under the same diagnostic umbrella. A child who avoids eye contact, flaps his hands, says only one or two words, and shows little interest in social interactions might share a diagnosis of ASD with a child who uses complex sentences and is socially motivated under certain circumstances but lacks the social awareness or skills to know how to behave in social situations or maintain successful peer relationships. Aided in part by advances in standardized diagnostic instruments and by opportunities to study larger and more diverse samples of individuals with ASD, there is increasing awareness that the spectrum of autism encompasses a wide range of difficulties and strengths and that no two individuals with ASD can be expected to look exactly the same.

Within the broader spectrum of autism, current diagnostic classification systems provide guidelines for assigning specific diagnoses (i.e., for determining whether a diagnosis of autism or Asperger syndrome or PDD-NOS is most appropriate). Unfortunately, these diagnoses tend to be highly unreliable across different sites and clinicians (Mahoney et al. 1998; Lord et al. 2012). Particularly with respect to Asperger syndrome, diagnostic conceptualizations vary widely within the field, making it difficult for professionals to agree on or be consistent in their use of terminology (Ozonoff et al. 2000). For example, whereas

some research groups adhere to the strict DSM-IV definition when diagnosing Asperger syndrome, which requires that autism be ruled out first, other groups diagnose Asperger syndrome even if the criteria for autism is also met (Szatmari et al. 2003). Similarly, although PDD-NOS is technically intended as a category to describe atypical autism (ICD-10) or “not quite autism,” it often ends up meaning “mild autism” or is used to classify young children to whom professionals do not yet feel comfortable giving an autism diagnosis (Walker et al. 2004). Disagreement about diagnostic criteria for differentiating within ASDs may help explain why, unlike earlier comparative studies, more recent investigations have not found clear differences between individuals identified as “high functioning autism (HFA)” and those diagnosed with Asperger syndrome. In one study, Bennett et al. (2008) found that adolescent outcomes in autism symptoms and adaptive behavior were better predicted by structural language impairment (defined by the presence of deficits in grammar or syntax) in childhood than by a clinical diagnosis of HFA vs. Asperger syndrome. Repetitive behaviors have also not been found to differ significantly between these diagnostic groups (Cuccaro et al. 2007).

Current Knowledge

From a clinical standpoint, the specific ASD diagnosis a child receives is arguably much less important than the fact that he/she falls somewhere on the autism spectrum. However, inconsistent use of labels often leaves parents confused about what to make of their child’s diagnosis. For example, Asperger syndrome has come to be portrayed in the media as a diagnosis characterized by special skills, high intelligence, and “quirky” personality traits, whereas autism is more commonly described as being associated with low IQ, limited language abilities, aloofness, and a poor prognosis. For parents of a child with ASD, their conceptualization of the disorder, including decisions about what interventions or

resources to seek out and expectations about the future, is likely to differ depending on whether the child receives a diagnosis of autism or another spectrum diagnosis that is perceived as being less severe. Moreover, if a child is initially given a diagnosis of PDD-NOS by one professional but then given a diagnosis of autism by another professional, the parent may erroneously assume that something about the child changed when in fact each professional simply had his/her own idiosyncratic way of deciding on one diagnosis over the other.

Disagreement about how diagnoses are assigned within the spectrum also has a number of important implications for ASD research. For example, if all “mild” cases of autism are referred to as Asperger syndrome or PDD-NOS, then a diagnosis of autism will be more likely to be related to intellectual disability. If Asperger syndrome is defined as any case of mild autism without intellectual disability, samples of children with PDD-NOS will be lower in IQ than if Asperger syndrome has a narrower definition (Klin et al. 2005).

From a neurobiological research perspective, clinical diagnostic designations are most useful if they are associated with different etiologies. But accumulating evidence suggests that these disorders are indeed on the same continuum and are therefore unlikely to be useful as a primary variable by which to stratify samples for etiological investigations. Analyses of datasets that include children with autism, PDD-NOS, and Asperger syndrome, as well as typically developing children and those with non-spectrum disorders, indicate that symptoms in the areas of communication, reciprocal social interaction, and restricted and repetitive behaviors constitute an “autism factor” that differentiates children with ASD *as a group* from children not on the spectrum (Constantino et al. 2004). Therefore, although the severity of symptoms in these domains differs among individual children with ASD, particular impairments in communication and reciprocal social interaction and the presence of restricted and repetitive behaviors set apart

individuals across the whole autism spectrum from those with other disorders (see also Lord and Bishop 2010).

Evidence that diagnostic distinctions within the spectrum may simply represent different degrees of the same disorder has also come from longitudinal follow-ups of children with ASD. Whereas movement “off” the spectrum is rare, it is not uncommon for children to change diagnoses within the spectrum depending on their symptom presentation at different points in development. A sizable proportion of children who initially receive a diagnosis of PDD-NOS in early preschool may go on to be diagnosed with autism in school age when their symptoms become more apparent and/or when the clinician becomes more certain about the diagnosis. Alternatively, some children diagnosed with autism may later receive a diagnosis of PDD-NOS when their symptoms improve (Lord et al. 2006; Stone et al. 1999). Such findings about changes in diagnostic status would be surprising if autism and PDD-NOS were indeed qualitatively distinct, but the concept of a spectrum allows for the idea that a child may move within the spectrum depending on their particular symptom profile while still continuing to meet the criteria for an ASD at each time point.

There is no question that the behavioral phenotypes of individuals with ASD are tremendously heterogeneous in general, or that an individual with a specific ASD designation of Asperger syndrome, for example, may look quite different than someone with a diagnosis of autism. However, research continues to indicate that whereas professionals (and diagnostic instruments) are reliable in indicating whether a child is somewhere on the spectrum or not on the spectrum, there are substantial inconsistencies in how specific ASD diagnoses are assigned by different practitioners (Lord et al. 2012). Therefore, it is likely that all specific ASD designations will be collapsed into a single ASD diagnosis in the forthcoming fifth revision of the DSM (see www.dsm5.org).

This proposed revision for DSM-V has caused significant controversy. Many professionals,

parents, and individuals with ASD feel that it is important to retain specific designations within the spectrum. Despite the issue of generally low levels of inter-rater reliability, it is argued that in some cases, diagnostic distinctions of autism vs. Asperger syndrome vs. PDD-NOS are useful or necessary in helping professionals communicate about different sorts of children or adults with ASD, or in helping families find resources that are appropriate. For example, parenting handbooks or social groups might be designed for individuals with “high functioning autism or Asperger syndrome” because the activities or suggestions are only relevant for those with fluent language. Similarly, a support group for parents of children with autism might be specifically intended to cater to families with children whose ASD symptoms are quite severe. Furthermore, some adults with ASD are more comfortable self-identifying as having Asperger syndrome (as opposed to autism or ASD) because they feel that this diagnosis more accurately reflects their profile of strengths and difficulties than the more classic definition of autism. Nevertheless, as they are currently defined, specific diagnoses within the spectrum have proven ineffective in reliably describing different groups of individuals with ASD.

On the other hand, the variability in language, cognitive functioning, and ASD symptoms and behaviors that exists among those diagnosed with ASD begs for *some* way of differentiating individuals with such discrepant behavioral profiles. Many authors have written about the need for measures of ASD severity. This information is necessary to facilitate communication about, and access to, appropriate services, as well as to measure the effectiveness of interventions and assess long-term outcomes. But the concept of ASD severity is still not well defined. Attempts have been made, through measures like the Social Responsiveness Scale (SRS; Constantino 2002), to develop more continuous measures of autism symptoms that can be used to approximate severity, but more research is needed to determine the extent to which scores on these

measures truly offer information about severity above and beyond what is provided by age and/or IQ. Often when people talk about a child at the “high end of the spectrum,” they are referring to the child’s high IQ or well-developed language abilities. Thus, putting the issues of IQ and language aside, it is not entirely clear what “severe” vs. “average” vs. “mild” ASD would be expected to look like. The ADOS calibrated severity score (Gotham et al. 2009) is a new metric that converts ADOS raw scores into standard scores based on comparisons of other children within the same age range and with similar language abilities. More research is needed to determine the validity of this score as a measure of ASD severity.

Future Directions

To begin to deal with the issue of severity in DSM-V, the proposed revisions stipulate that a diagnosis of ASD will be described in terms of severity in two domains: social-communication symptoms and fixated interests/repetitive behaviors. Any associations with other known genetic or medical conditions, language disorders, intellectual disability, or psychiatric disorders will also be specified (see www.dsm5.org). It will be important to evaluate whether this dimensional approach to “within-ASD” designations results in enhanced inter-rater reliability among professionals compared to the current categorical approach. In addition, it will be important to examine the utility of the new severity dimensions for both clinical (e.g., using different severity designations to track children into various services) and research (e.g., as predictors of outcome to stratify genetics samples) purposes. Undertaking other measure development efforts in the area of ASD severity may also be helpful in providing a means of operationalizing various anchor points along the spectrum (e.g., mild vs. severe ASD) or along multiple spectra (i.e., defined by more narrow behavioral dimensions) relevant to a diagnosis of ASD.

Definition

Speech is the physical production of language. Speech is a complex act that requires the coordination of multiple systems including respiration, voicing, articulation, and prosody. Speech begins with respiration. Respiration provides the air supply necessary to create speech sounds, also known as phonemes. As the air moves through the vocal tract into the larynx, the vocal folds are vibrated to produce voiced sounds (e.g., /g/) or remain still to produce voiceless sounds (e.g., /h/). Once the air moves out of the larynx, it continues through the vocal tract and into the mouth where the air is

shaped into sounds by the articulators (e.g., lips, teeth, and tongue). Accurate speech sound production requires appropriate timing, direction, force, speed, and placement of the articulators (American Speech-Language-Hearing Association n.d.; Freed 2000; Zemlin 1998). Producing speech enables individuals to communicate (e.g., expressing wants and needs, asking for information or help).

Speech Delay

Allison Bean Ellawadi

Speech and Hearing Science, The Ohio State University, Columbus, OH, USA

Definition

Speech delay is the diagnosis given to children who exhibit normal language development, but their speech production skills fall below those expected based on their chronological age and level of cognitive or intellectual functioning (Vinson 2007). Speech-language pathologists use standardized language tests to diagnose speech delay. While the etiology underlying the delay may be unknown, speech delay has been associated with a variety of developmental disorders including autism spectrum disorders. Predictors of long-term speech delay in late-talking toddlers at 30–35 months include limited phonetic inventory, simple syllable structures, more sound errors, greater inconsistency in substitution errors, atypical errors, and slow rate of resolution (Williams and Elbert 2003). Speech therapy may be provided to children with a diagnosis of speech delay with the goal of helping them attain communication skills that are commensurate with their chronological/developmental age (Roth and Worthington 2010).

[Speech disorder](#)

Definition

Speech impairment is the diagnosis given to an individual when one or more of the components of speech (e.g., articulation, voice, fluency) are

impaired. Speech-language pathologists use standardized tests to diagnose speech impairments. The different categories of speech impairments reflect the underlying etiology of the disorder and/or the impaired components. Childhood speech impairments include apraxia, dysarthria, speech sound disorders, stuttering, and voice. Adult speech impairments include apraxia, dysarthria, stuttering, and voice. An individual's speech impairment may emerge over the course of development, be acquired due to a brain injury, or be associated with a disorder such as cerebral palsy (American-Speech-Language-Hearing-Association n.d.). Speech-language pathologists work with individuals with speech impairments to either help them attain communication skills that are commensurate with their chronological/developmental age or premorbid status or to help them attain functional communication skills that enable them to operate in the daily environment without handicap (Roth and Worthington 2010).

Speech Morphology

Maura Moyle and Melissa Manjarrés
Speech Pathology and Audiology, Marquette
University, Milwaukee, WI, USA

Synonyms

[Affixes](#); [Bound morphemes](#); [Grammatical morphemes](#)

Definition

Speech morphology deals with the organization of morphemes, or the smallest units of meaning, in spoken language. Morpheme arrangement is governed by morphological rules and, in spoken language, by morphophonological rules. In speech, these rules dictate when pronunciation changes result from the combination of morphemes (e.g., *divine* + *ity* to form *divinity*).

Morphemes are categorized according to structure and function. Free morphemes can stand alone (e.g., *cat*), while bound morphemes must be attached to a free morpheme (e.g., plural *-s*). Bound morphemes can be classified as derivational or inflectional. Derivational morphemes change the class of a word (e.g., the verb *work* is changed to a noun by adding the morpheme *-er*, as in *work* → *worker*), while inflectional morphemes are associated with grammatical changes (e.g., plural, possessive, verb tense). While some individuals with autism spectrum disorders may exhibit normal morphological aspects of speech and language, others may exhibit deficits in grammatical morphology similar to those observed in children with specific language impairment (SLI). There is evidence to indicate that children with SLI have particular difficulty with finite verb morphology.

Speech Therapy

Allison Bean Ellawadi
Speech and Hearing Science, The Ohio State
University, Columbus, OH, USA

Definition

Speech therapy is a treatment aimed at modifying, minimizing, or resolving a communication disorder (Tomblin 2002).

Historical Background

The first speech defects and treatments were reported in the third and fourth century BC (Klingebeil 1939). The roots of modern day logopedics, known as speech therapy in the United States, began on the European continent (Rieber and Froeschels 1966). The first center that took a special interest in speech functioning and rehabilitation was established in 1895 and located in Vienna. The work at this center was carried out by physicians who went on to form the profession of phoniatics (the medical, research, and treatment of structures involved in speech production). In 1921, a phoniatriest and educationalist came together to initiate a training program for teachers that focused on teaching speech, and by 1928, 39 schools in Vienna were offering remedial speech courses. In the 1900s, Americans began to travel to Germany and other European countries to study speech. As the number of speech practitioners in Europe grew, a decision was made to host an international

congress in 1924, which focused on various aspects of communicative disorders. The International Association of Logopedics and Phoniatics was founded during this congress (DeMontFort 1990).

During this same time, graduate programs were beginning to develop in the United States. One of the first graduate programs was established in 1914 at the University of Wisconsin by Smiley Blanton. In the United States, the first practitioners of speech pathology were professionals and educators who took an interest in helping individuals with speech problems. These practitioners, referred to as “speech correctionists,” were made up of physicians, scholars, and public school administrators all of whom fell under the National Association of Teachers of Speech. In 1925, Carl Seashore, a professor of psychology at the University of Iowa, initiated a meeting aimed at forming an academy for speech correction that was independent of the National Association of Teachers of Speech. The outcome of this meeting was the formation of the American Academy of Speech Correction, which would eventually go on to become the American Speech-Language-Hearing Association (Duchan 2002; van Riper 1981). The number of members of the American Speech-Language-Hearing Association has grown from 25 members in 1925 to 175,673 members in 2016 (American Speech-Language-Hearing Association 2017). Although the roots of modern speech therapy began in Europe and the United States, today, clinicians provide speech therapy to individuals with communicative disorders throughout the world. However, there are significant differences in the length and content of the training programs. Many countries with limited resources do not have training programs even though these countries have citizens with hearing, speech, and language problems. Thus, a primary goal of the International Association of Logopedics and Phoniatics is to establish an international set of essential principles and common ground for those who serve individuals with communication disorders throughout the world (Butler 1990).

Rationale or Underlying Theory

Communication is an essential social tool. Communication is considered disordered when an individual is no longer able to accomplish necessary social functions or the manner in which an individual communicates is viewed negatively (Tomblin 2002). The overall goal of speech therapy is to modify, minimize, or resolve an individual's communication disorder and subsequently improve his or her quality of life. To accomplish this, the speech-language pathologist must identify factors causing and/or exacerbating the problem and then provide appropriate treatment. Treatment may be aimed at targeting areas of weakness, providing support or alternative methods of communication, and/or addressing behaviors and environments that affect communication (Tomblin 2002).

Goals and Objectives

The objective of speech therapy varies depending on the individual. Goals most often fall into one of the two categories: (1) the attainment of communication skills that are commensurate with the individual's chronological/developmental age or premorbid status or (2) the attainment of functional communication skills that enable the individual to function in his or her daily environment (Roth and Worthington 2001).

Treatment Participants

Individuals with a diagnosed communicative disorder are eligible for speech therapy. Communicative disorders do not include speech and language differences that arise from dialect usage or nonnative language (Roth and Worthington 2001).

Treatment Procedures

The treatment of a communicative disorder begins with an assessment of the individual's

communication behaviors. Treatment involves the following steps: (1) determination of treatment goal(s), (2) measurement of the behavior prior to the start of intervention for the purpose of establishing a pretreatment baseline, (3) implementation of intervention, and (4) generalization or carryover of the newly mastered communicative behavior from the clinical setting to the natural environment (Hedge 1988; Roth and Worthington 2001).

Treatment goals may be determined using either a normative or client-specific strategy. The normative strategy for treatment goal selection is based upon typical communication development. Therapy targets are selected and taught in the same order that they emerge developmentally. Normative goal selection is most often used with children who are receiving therapy to address articulation and/or language impairments. Client-specific goal selection involves selection of therapy targets based on an individual's specific needs rather than developmental norms. This includes "consideration of (1) the frequency with which a specific communicative behavior occurs in a client's daily activities, (2) the relative importance of a specific communicative behavior to the client, regardless of how often it occurs, (3) the client's potential for mastery of a given communication skills" (Roth and Worthington 2001, p. 7).

There are often a variety of treatment methods available to target the selected treatment goal. Speech-language pathologists use evidence-based practice, which is the integration of clinical expertise with the best available evidence from systematic research, to determine what intervention method and/or therapy techniques to use (Dollaghan 2007; Reilly et al. 2004).

A baseline measurement of the behavior that will be targeted during speech therapy should be taken prior to the start of intervention. Baseline measures provide a picture of the individual's communicative behaviors prior to treatment and a base against which the effects of various treatments may be measured. More specifically, baseline measurements enable a clinician to document whether or not the targeted behavior has improved. Without pretreatment baseline

measures, clinicians are unable to document whether an intervention was or was not effective (Hedge 1988).

Finally, clinicians must determine whether or not the targeted behavior has been mastered. Mastery of a behavior includes generalization of a targeted behavior to outside of the clinical setting. To facilitate generalization, a variety of stimuli should be used when teaching the targeted behavior, and the audience with whom the therapy targets are practiced should be varied (Roth and Worthington 2001).

Efficacy Information

The National Outcomes Measurement System (NOMS), organized by the American Speech-Language-Hearing Association, is a national database comprised of outcome data from speech-language pathologists (SLPs) and audiologists working with adults and children in school and health-care settings. The results from this database indicate that speech therapy is effective at modifying, minimizing, and/or resolving communication disorders. In the area of adult treatment, intervention is considered effective if there is measurable change from admission to discharge. Measurable changes for patients were found in the areas of memory, swallowing, motor speech, language comprehension, and expression (American Speech-Language-Hearing Association *n.d.-b*). In the area of child treatment, children must make demonstrable progress in targeted areas. Results from prekindergarten data found that more than half of the children made demonstrable progress following SLP intervention in the areas of articulation/intelligibility, cognitive orientation, pragmatics, spoken language comprehension, spoken language production, and swallowing. This included children with lower functional communication and/or swallowing abilities. Thus, the data suggests that speech therapy is effective, as demonstrated by measuring change, in treating both adult and child communicative disorders (American Speech-Language-Hearing Association *n.d.-a*; American Speech-Language-Hearing Association *n.d.-b*; Mullen and Schooling 2010).

Outcome Measurement

To determine outcome measurements, clinicians should compare pretreatment baseline measures to posttreatment measures and/or compare scores from admission and discharge. The differences in pretreatment and posttreatment measures may be used to determine the amount of change that has occurred as a result of treatment (Hedge 1988). The National Outcomes Measurement System, organized by the American Speech-Language-Hearing Association, uses functional communication measures to describe the change in an individual's functional communication and/or swallowing ability over time. These measures are based on disorder-specific scales (Mullen and Schooling 2010).

Qualifications of Treatment Providers

Qualifications needed to provide speech therapy services in the United States include Certification of Clinical Competence (CCC). This certificate, granted by the American Speech-Language-Hearing Association, requires a master's degree from an accredited graduate program, a passing score on the national Praxis exam (a certification examination written and administered by the Educational Testing Service), and completion of a 9-month clinical fellowship under the supervision of a certified speech-language pathologist. Most states license speech-language pathologists. State licensing requirements are most often comparable, although they may not be identical, to the qualifications for the Certificate of Clinical Competence. Speech-language pathologists licensed in other states must apply for licensure in the state in which they are practicing (American Speech-Language-Hearing Association *n.d.-c*).

Speech/Communication Disabilities

Maura Moyle and Steven Long
Speech Pathology and Audiology, Marquette
University, Milwaukee, WI, USA

Synonyms

Communication disorder; Language impairment/disorder; Speech impairment/disorder

Short Description or Definition

Speech/communication impairments are among the core features of autism spectrum disorders (ASD). Although enormous variability in the development of speech and language is observed in individuals with ASD, even those who have high cognitive and language abilities exhibit some type of communication disability. Deficits can occur at the nonverbal level (e.g., gestures, facial expressions, eye gaze), paralinguistic level (e.g., prosody, intonation), and linguistic level (e.g., language, speech). Communication deficits in the social use of speech and language are particularly salient. Research suggests that a subset of children with ASD also have grammatical deficits similar to children with specific language impairment. In addition, speech sound disorders are evident in a subset of children with ASD. Approximately 20–40% of individuals with autism never develop spoken language, and about 20% exhibit a loss of language skills as toddlers, also known as language regression.

Aspects of communication that are relatively preserved in individuals with ASD include segmental phonology (i.e., the system of speech sounds), syntax, and morphology (i.e., the form or structure of language). Areas of relative difficulty include nonsegmental speech production (e.g., prosody, intonation, stress patterns, vocal quality), semantics (i.e., meaning), and pragmatics (i.e., social use of language).

Speech Therapy (Not Preferred)

► Speech-Language Intervention

Categorization

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5; American Psychiatric Association 2013) includes four categories of communication disorders: language disorder, speech sound disorder, childhood-onset fluency disorder, and social (pragmatic) communication disorder. Speech/communication disabilities can be associated with developmental disabilities and syndromes, such as autism spectrum disorders.

Epidemiology

Speech/communication disabilities are core features of ASD. According to Fombonne's (2009) review, the prevalence for all autism spectrum disorders (previously referred to as pervasive developmental disorders) is estimated at 60–70 per 10,000.

Natural History, Prognostic Factors, Outcomes

Communication delays and deficits are often the first indicators of ASD. For example, children later diagnosed with ASD show a lack of interest in faces, voices, and social interactions as infants. Later in development, children with ASD may fail to understand or produce communicative gestures (e.g., pointing) and may be delayed in babbling, vocalizing, and speech development. Lack of communication skills is one of the most significant stress factors for families of children with ASD.

The speech/communicative outcomes of individuals with ASD are extremely variable. About 20% of children with ASD exhibit a regression in speech and language skills during their second year of life. About 40–50% never develops functional speech except for perhaps a few single words (although this percentage may be decreasing due to the positive effects of early identification and intervention). Little is known about the communication skills of nonverbal individuals with ASD because research has focused on verbal individuals.

Those individuals with ASD who do develop speech are often significantly delayed and do not speak until well into their preschool years. High-functioning individuals with ASD may have IQs in the normal range and appear precocious in their vocabulary size and ability to speak in detail on certain topics. Despite these strengths, this population continues to struggle with the comprehension and production of social and non-literal communication.

Several characteristics have been linked to better communicative outcomes. For example, children with ASD who produce and imitate words, exhibit pretend play with objects, communicate with gestures, and show evidence of joint attention have greater rates of vocabulary growth and overall language skills. Negative prognostic indicators include a regression in language skills after a period of development and severe receptive language impairment. Children with lower IQs also tend to have poorer communicative functioning. Even for individuals with high cognitive and language abilities who attend college and are able to live independently, ASD is a lifelong disability that affects social communication and functioning.

Clinical Expression and Pathophysiology

Early Communication Development

Communication is a broad term that encompasses numerous modes of sending and receiving messages, including gestures, body language, facial expressions, language, and speech. Typically developing children exhibit social communicative behaviors beginning in infancy. For example, they turn toward human voices, are fascinated by faces, smile to hold an adult's attention, vocalize, and demonstrate joint attention (e.g., paying attention to the same object as another person). In the first year of life, typically developing infants express a range of communicative intents, such as requesting, greeting, and protesting. For individuals with ASD, communication deficits are apparent almost from birth. One of the first signs of ASD is a lack of responsiveness to social interactions. For example, infants later diagnosed with ASD were described by their

parents as uninterested in human voices or faces. They rarely smiled at others, vocalized in a communicative manner, or engaged in social games such as “peekaboo.” In addition, 1-year-olds who were later diagnosed with ASD exhibited a lack of joint attentional behavior and paid less attention to people in their environment. The communicative intents of children with ASD are primarily to regulate their environment (e.g., getting others to do things for them) rather than for social purposes. They may exhibit unusual gestures, such as pulling an adult’s hand toward a desired object (rather than pointing at the object or verbally requesting it). Other symptoms of communicative deficits include delayed development of pointing gestures, a lack of typical imitation skills, and deficits in pretend and imaginative play. In the second year of life, the receptive language abilities of children with ASD are depressed relative to their expressive abilities. The gap tends to narrow over time, with receptive and expressive language abilities becoming more similar by ages 3–4. Parents of children with ASD report becoming seriously concerned about their children’s development during the toddler years, particularly due to their children’s receptive and expressive language delays. Children with ASD are generally late to begin talking and develop speech and language at a slower rate than typical children. When they do speak, children with ASD are less spontaneous in their communication, and verbal expression is sparse. They also exhibit deficits in social communication, including following politeness rules, turn taking, and engaging in conversation.

Later Language, Speech, and Communicative Development

Language consists of three primary domains: form, content, and use. *Form* involves the structure of language (i.e., phonology, syntax, morphology), *content* involves the meaning of language (i.e., semantics, vocabulary), and *use* refers to the social use of language (e.g., pragmatics). Effective communication involves the interaction of these three domains. For example, language produced by typical individuals is most often syntactically correct, meaningful, and socially

appropriate. In addition, effective communicators can decode other’s communication in terms of its form, content, and use. In individuals with ASD, the domains of language can be dissociated, negatively impacting communication. Specially, the form of language may be preserved (e.g., syntax, morphology, phonology), but the meaning, and especially social use of language, is impaired. More details on the language, speech, and communication characteristics of individuals are included below.

Language Form (Phonology, Morphology, Syntax)

The language form of individuals with ASD who communicate verbally is relatively unimpaired compared to the language domains of content and use. In general, development of language form in children with ASD follows the same sequence as for typically developing children. Syntactic errors that are observed seem to be related to semantic or pragmatic difficulties. In general, the development of language form is commensurate with nonverbal mental age, although a more restricted range of syntactic constructions may be produced. A subgroup of children with ASD may exhibit grammatical deficits similar to children with specific language impairment. This subgroup of children is likely to omit certain grammatical morphemes such as articles, auxiliary and copula verbs, and verb tense markers (e.g., past tense, third person singular).

Language Content (Vocabulary, Semantics)

Language content involves the rules for relating words to meaning. Individuals with ASD exhibit both strengths and impairments in this language domain. For example, research suggests that overall vocabulary knowledge may be a relative strength in individuals with autism spectrum disorders (ASD). In addition, children with ASD use semantic groupings (i.e., word relationships) in typical ways for categorizing and retrieving words. Despite these strengths, notable deficits and unusual characteristics are apparent. For example, the acquisition of words that refer to mental state or emotional concepts may be especially impaired. Individuals with ASD may

have difficulty generalizing the meanings of words to new contexts (e.g., understanding that the word “dog” can refer to many animals, not just the family pet). In addition, they often have difficulty comprehending vocabulary in nonliteral language (e.g., slang, figures of speech, proverbs, metaphors).

Individuals with ASD may produce speech that appears to be irrelevant to the current communicative context. These utterances are referred to as idiosyncratic or metaphorical language. For example, Kanner (1946) described a child with ASD who would yell, “Don’t throw the dog off the balcony!” whenever he was about to throw something. His parents reported that several years earlier, they had been staying in a hotel with a balcony and warned the child not to throw his stuffed toy dog over the railing. Kanner emphasized that this type of utterance was not irrelevant or meaningless. Rather, individuals with ASD attach unique meanings to these “figures of speech” based on specific past experiences.

Language Use (Pragmatics, Social Use of Language)

The social use of language is particularly impaired in individuals with ASD, including for individuals with IQs in the normal range. Deficits in social communication are evident almost from birth, as children with ASD are less responsive to voices and faces. Social skills are learned and applied in transactional contexts, that is, during interactions between communication partners. The deficits in social communication in individuals with ASD result in less social experience, contributing to impaired development and learning. For children who develop verbal language, the speech acts they do exhibit are primarily for regulating their environment and the behaviors of others, rather than for social purposes. Later in development, engaging in conversation appears to be especially difficult. Deficits in eye gaze, intonation, topic maintenance, understanding the communicative intent of others, and providing the appropriate amount of information are apparent. In general, individuals with ASD exhibit impairments participating in communicative interactions

that involve joint reference or shared topics and perspectives.

Speech

Among individuals with ASD who speak, articulation skills are a relative strength and are generally commensurate with mental age, although there may be a higher incidence of residual speech distortion errors on sounds such as /r/, /l/, and /s/ in adults. Despite strengths in speech sound development, paralinguistic aspects of speech (e.g., intonation, prosody) and vocal quality may be atypical, causing communication difficulties. For example, prosody and intonation may be monotonous, inappropriate, or overly dramatic. In addition to expressive deficits, individuals with ASD may have difficulty interpreting the prosody and intonation of others leading to misinterpretation of sarcasm, etc.

Echolalia

Echolalia is the repetition, with similar intonation, of words or phrases spoken by another person. Echolalia can be immediate (e.g., a child repeats, “Are you hungry?” when an adult asks him that question) or delayed (e.g., a child says, “You look sleepy,” to indicate that it is bedtime). Echolalia was once considered to be aberrant, undesirable behavior. Now it is recognized as serving various communicative functions. Echolalia is more common in children with less language ability and tends to decline as language develops. Other populations of children, including typical children, also produce echolalic utterances, although not to the extent observed in children with ASD.

Pronoun Reversal

It has frequently been noted that children with ASD appear to reverse the pronouns in their utterances. For example, they may say, “Pick you up!” instead of, “Pick me up!” These errors are thought to be a result of echolalia.

Evaluation and Differential Diagnosis

As stated earlier, impairments in communication, particularly for social purposes, are core features

of ASD. Therefore, all individuals with ASD will have communication needs, although they will vary depending on the age, level of functioning, and individual characteristics of each person. For very young children, assessment will include evaluation of preverbal communication abilities, including gestures, eye gaze, joint attention, vocalizations, responsiveness to communication, and communicative functions. Observations during play or activities of daily living are important for gaining information about children's communicative behavior and their caregivers' interactional style. The use of checklists while observing the child in naturalistic interactions is common and may be the only feasible method of assessment for many children with ASD who have difficulty participating in structured test formats (see Paul and Norbury 2012).

A variety of parent report/interview assessment tools are available, including the *Receptive-Expressive Emergent Language Test, Third Edition* (REEL-3; Bzoch et al. 2003) and the *Vineland Adaptive Behavior Scales, Third Edition* (Vineland-3; Sparrow et al. 2016). Other assessment tools include direct observation of the child and may include more structured interactions or elicitation of particular behaviors. Examples include the *Communication and Symbolic Behavior and Play Scales-DP* (CSBS; Wetherby and Prizant 2003), the *Peabody Picture Vocabulary Test, Fourth Edition* (PPVT-5; Dunn 2019), and the *Preschool Language Scale, Fifth Edition* (PLS-5; Zimmerman et al. 2011).

In verbal children, language samples may be collected for assessing the expression and use of language in naturalistic settings. Specific areas to assess include responsiveness to speech, mean length of utterance (a measure of syntactic development), word use, echolalia, pronoun use, and pragmatics. Pragmatic analysis may include the range of communicative functions (e.g., directing others, reasoning, empathizing), discourse management, register variation (e.g., politeness), presupposition (e.g., providing enough background information), and manner of communication.

For individuals with ASD who have higher cognitive and language abilities, and who can

participate in formal testing situations, a variety of standardized language assessments are available (see Paul and Norbury 2012). Assessments that focus on pragmatic language or verbal reasoning may be the most useful in identifying core deficits. It is important to supplement standardized testing with informal observations within a variety of naturalistic contexts in order to capture deficits in social communication.

For individuals with ASD who are nonverbal, it is important to assess the various ways that they do communicate. In addition, their ability to use augmentative and alternative communication (AAC) may also be evaluated.

Speech can be assessed through procedures common to the evaluation of any client with a suspected speech sound disorder, depending on the ability of the individual with ASD to participate in a standardized assessment. Common tests include the *Arizona Articulation Proficiency Scale, Fourth Edition* (Arizona-4; Fudala and Stegall 2017) and the *Goldman-Fristoe Test of Articulation 3* (GFTA-3; Goldman and Fristoe 2015). Also, speech can be evaluated through more naturalistic sampling procedures (e.g., recording an inventory of a client's phonetic repertoire during spontaneous speech).

Treatment

For individuals with ASD, research has demonstrated that a range of approaches are effective for promoting communication abilities (cf. ASHA 2017). Common approaches range from naturalistic (e.g., Floor Time, Greenspan et al. 1998) to highly structured, behavioral interventions (e.g., Lovaas et al. 1989). The incorporation of peers as models and/or trainers is also common. According to the National Research Council (2001), educational interventions for individuals with ASD should begin as early as possible, programming should be intensive with repeated and planned teaching opportunities, teacher-student ratios should be low, mechanisms for ongoing assessment and program evaluation should be in place, and family involvement and training is important.

In addition, intervention for individuals with ASD should include spontaneous and functional communication, social skills, play skills, peer interactions, generalization of skills to natural contexts, mechanisms for addressing challenging behaviors, and promoting functional academic skills when appropriate.

For young children in the beginning stages of language development, the goals of intervention include rewarding efforts for communication and speech, expanding vocabulary and communicative functions, encouraging multiword utterances, expanding sentence types, developing emergent literacy, teaching functional use of imitation, and capitalizing on memorized forms. Various evidence-based approaches to facilitating language may be implemented, including prelinguistic milieu teaching, focused stimulation, and conversational recasting. In addition, approaches that focus on parent training, such as *It Takes Two to Talk, More Than Words or Talkability* (developed by The Hanen Centre), have been shown to be effective.

For nonverbal individuals with ASD, the use of augmentative and alternative communication (AAC) strategies is common for facilitating communication. AAC approaches include sign language, Picture Exchange Communication System (PECS), communication boards, and voice output devices. For individuals who are literate, written language can be an effective means of communication and can be used for compensatory purposes (e.g., using a script or communication checklist for functioning within various situations). For example, Social Stories (Gray 1993) employ a story format using visual materials to improve an individual with ASD's social understanding of various situations. Technology (e.g., texting, social networking) may assist individuals with ASD in social communication without the stress of face-to-face interactions. Comprehension monitoring strategies for older individuals with ASD with higher cognitive and language abilities (e.g., checklists) may also be effective.

In general, intervention for individuals with ASD needs to address core deficits in communication and social skills.

Definition

The overall objective of speech-language therapy or speech-language pathology services is to optimize individuals' ability to communicate and swallow, thereby improving quality of life. Speech-language pathologists are the professionals who provide speech, language, and swallowing evaluations and treatment. Speech-

Speech Disorders

- Speech sound production – how we say sounds and put sounds together in words
- Fluency (stuttering) – how well speech flows
- Voice – how the voice sounds
- Speech-language therapy – focuses on improving articulation or pronunciation of sounds, improving fluency in increasingly longer utterances, and helping people who sound hoarse, lose their voice easily, talk too loudly or too softly, or talk through their nose

Language Disorders

- Spoken language – how well we understand what we hear and how well we use words to tell others what we are thinking. Loss of language following a stroke or brain injury is known as *aphasia*.
- Written language – how well we understand what we read, how well we read, and how well we write to communicate.
- Speech-language therapy – helps individuals who have problems understanding, speaking, reading, writing, and spelling.

Social Communication or Pragmatic Language Disorders

Social communication, or *pragmatics*, refers to the way in which individuals use language in context. This is one of the defining features of autism. It includes following rules for conversation, such as taking turns, staying on topic, describing an event in sequence, and talking differently depending on the listener and the setting.

Speech-language therapy focuses on helping people adapt their language use depending on the

listener and the setting, learn the rules of conversation and storytelling, and use nonverbal language correctly (e.g., using gestures, knowing how close to stand when someone is talking).

Cognitive-Communication Disorders

People may have problems with memory, attention, problem solving, organization, and other thinking skills that interfere with effective communication.

Speech-language therapy helps individuals with organizing thoughts, recalling information, paying attention, planning, and solving problems.

Severe Communication Disorders

Speech-language therapy is used to assist people with severe communication disorders by providing direct service, by collaborating with teachers and families, and by evaluating, selecting, and developing augmentative and alternative communication (AAC) systems. Such systems may include low-tech communication boards with words or pictures, sign language, and speech-generating devices that produce a synthesized voice through use of a computer.

Feeding and Swallowing Disorders (Dysphagia)

People may have problems sucking, chewing, and swallowing food and liquid; this is known as *dysphagia*. Intervention helps to prevent poor nutrition, weight loss, and other health problems in individuals with dysphagia.

SLP (acronym for speech-language pathologist); Speech clinician (not preferred title); Speech pathologist (not preferred title); Speech teacher (not preferred title); Speech therapist (not preferred title); Speech-language clinician (not preferred title); Speech-language therapist (not preferred title)

Definition

The American Speech-Language-Hearing Association (ASHA) is the national professional, scientific, and credentialing association for 211,000 members and affiliates who are audiologists; speech-language pathologists; speech, language, and hearing scientists; and audiology and speech-language pathology support personnel. According to ASHA, *speech-language pathologists* are the professionals responsible for the diagnosis, prognosis, prescription, and treatment of speech, language (spoken and written), cognitive communication, social communication, and swallowing disorders. Working within the full range of human communication and its disorders, speech-language pathologists evaluate and treat individuals of all ages who have difficulty speaking, understanding, reading, writing, or swallowing. Individuals with autism typically present with communication disorders, including

delayed speech and language as well as social communication disorders. Speech-language pathologists are often the first professionals to identify that a child has autism. Speech-language pathologists screen, assess, diagnose, and provide intervention services for children and adults with autism. Speech-language pathologists may work independently or as members of a team. In addition, speech-language pathologists may:

- Train future professionals at colleges and universities
- Manage agencies, clinics, or private practices
- Engage in research to enhance knowledge about human communication processes
- Develop new methods and equipment to evaluate problems
- Establish more effective treatments
- Investigate behavioral patterns

Speech-language pathologists, as defined by ASHA, hold the ASHA Certificate of Clinical Competence in Speech-Language Pathology (CCC-SLP). Minimal criteria to become a speech-language pathologist include:

- Master's, doctoral, or other recognized post-baccalaureate degree.
- All graduate coursework and graduate clinical experience required in speech-language pathology must have been initiated and completed in a program accredited by the Council on Academic Accreditation in Audiology and Speech-Language Pathology (CAA) or in a program with CAA candidacy status.
- Successful passing of a national examination in speech-language pathology.
- Completion of a clinical fellowship after completion of academic course work and clinical practicum – the fellowship consists of at least 36 weeks and 1,260 hours, which can be completed full-time or part-time.

Demonstration of continued professional development is mandated for maintenance of the CCC-SLP. Where applicable, speech-language pathologists hold other required credentials (e.g., state licensure, teaching certification).

Sports

Ernst O. VanBergeijk
 Vocational Independence Program, New York
 Institute of Technology, Central Islip, NY, USA
 Threshold Program, Lesley University,
 Cambridge, MA, USA

Definition

Sports are physical activities that usually require exertion, effort, and skill. They can be

individual or team oriented and require athletic ability. Many sports are competitive in nature where one individual or team attempts to beat another in a game or in the achievement of a goal. Sports can be played both indoors and outdoors.

Historical Background

The inclusion of individuals with autism spectrum disorders in the USA in sports can be traced directly to the creation of the Special Olympics. Eunice Kennedy Shriver was the founder of the Special Olympics which started as a summer day camp program for children with intellectual disabilities in her own backyard in 1962. In 1968, the first international Special Olympics were held at Soldier Field in Chicago, IL, with athletes from 26 states and Canada competing in track and field and swimming events. Over the past 40 years, the organization has grown to a global movement. It now includes both summer and winter Olympic Games and involves over 3 million athletes in 180 countries (Special Olympics 2011).

A second origin of the inclusion of individuals with autism in sports can be traced back to educational law. In 1975, the Education for All Handicapped Children Act, more commonly referred as P.L. 94-142, made education a right for all children with disabilities. Children with disabilities could no longer be denied an education. It was incumbent upon the local education agency or school district to provide a free and appropriate public education (FAPE) to all children with disabilities. Along with the legal concept of FAPE was the concept of mainstreaming. It was not sufficient for school districts to simply educate students with disabilities separately from nondisabled students. School districts were required to “mainstream” students for an optimal time period that was individualized to the particular student. Physical education classes along with art, lunch, recess, and some academic subjects were written into Individualized Education Plans (IEPs) of students as areas in the curriculum where students with disabilities were mainstreamed or educated side by side with their nondisabled peers.

This landmark legislation also included the concept of ancillary services, i.e., services provided to the student that were not directly educational in nature but helped to support the student in reaching his or her educational goals as a part of his or her IEP. Physical therapy, occupational therapy, and adaptive physical education were some of those ancillary services that helped individuals with autism participate in sports not only in the public school systems but eventually in the greater community as well. P.L. 94-142 was subsequently reauthorized as the Individuals with Disabilities Act (IDEA) and reaffirmed the importance of educating students with disabilities side by side with their nondisabled peers, and the concept of mainstreaming evolved into the concept of inclusion. Physical education classes were one of the primary parts of the curriculum where inclusion was written into a student's IEP. Under IDEA, physical therapy and adaptive physical education were solidified as ancillary services to support students with autism in reaching their IEP goal and helped pave the way to including individuals with autism in sports.

A tertiary influence on the inclusion of individuals with autism in sports needs to be credited to individuals with physical disabilities. In fact, the Paralympics movement predates Special Olympics and the passage of legislation in the USA promoting access for people with disabilities. "In 1948, Sir Ludwig Guttmann organized a sports competition involving World War II veterans with a spinal cord injury in Stoke Mandeville, England. Four years later, competitors from the Netherlands joined the games and an international movement was born. Olympic style games for athletes with a disability were organized for the first time in Rome in 1960, now called Paralympics. In Toronto in 1976, other disability groups were added and the idea of merging together different disability groups for international sport competitions was born. In the same year, the first Paralympic Winter Games took place in Sweden" (International Paralympic Committee 2011).

Disabled veterans and other groups of individuals with physical disabilities fought for access to services and the basic right to not be denied

physical access. These groups fought for the passage of the Vocational Rehabilitation Act of 1975 including Section 504 which forbade public entities which received federal funding from denying the benefits of the services of the institution solely based upon a person's disability. In 1990, the act was reauthorized and renamed as the Americans with Disabilities Act (ADA). These movements contributed to the rise of adapted physical activities where the sports or the equipment were modified so that individuals with physical disabilities could participate in sports. Modifying the social rules of some team sports for individuals on the autism spectrum, therefore, was made easier by these previous modifications. The importance of these movements changing the culture from exclusion to inclusion of people with different abilities cannot be underestimated when considering the inclusion of people with autism in sports.

Current Knowledge

It is imperative that individuals with ASDs develop lifelong habits that incorporate fitness into their daily routine. Sports can be a part of that fitness regime. The USA is faced with an obesity epidemic with over two-thirds of Americans being labeled as overweight or obese (Center for Disease Control [CDC] 2010). Sedentary lifestyles and diet are major contributors to obesity. The sequelae of obesity are serious including heart disease, diabetes, and certain forms of cancer (CDC 2010; Rundle et al. 2010). Additionally, obese individuals suffer a lowered quality of life and are actively discriminated against (CDC 2010). For children, being overweight puts them at greater risk for being the victim of bullying and increased risk of suicidality (CDC 2011a). Individuals who are obese also suffer from a shortened lifespan. The average American will live 77.9 years (CDC 2011b). Those who are labeled obese are expected to decrease not only their own life expectancy but that of the US population as a whole (Steward et al. 2009). However, a positive relationship exists between exercise and longevity. Individuals who exercise regularly have reduced mortality from all causes (Blair

and Brodney 1999; Paffenbarger et al. 1986). For individuals on the autism spectrum, regular moderate to vigorous exercise is associated with increased attention span, a decrease in stereotypies (Elliott et al. 1994), and a decrease in the use of psychotropic medications. Participation in sports is one way for individuals with ASDs to exercise regularly.

Individuals on the autism spectrum are at increased risk for developing obesity. One national health study of children found that children with an ASD were 42% more likely to be labeled obese than children without an ASD (Curtin et al. 2010). In fact, obesity is a well-recognized issue among people with developmental disabilities. A number of factors contribute to individuals with ASDs being more vulnerable to obesity. First, many individuals on the spectrum take medications to treat comorbid psychiatric and behavioral issues, which have either increased appetite or weight gain as a side effect. Second, some individuals on the spectrum have very restrictive self-imposed diets that are high in fat and have little nutritional value. In fact, anecdotal stories of individuals with ASDs eating only “white foods” such as breads and plain pasta suggest that they have a diet replete with carbohydrates that are associated with weight gain (VanBergeijk 2009). Third, some people with ASDs have both coordination problems and problems with proprioception (Weimer et al. 2001) or the ability to know where one’s own body is in space. Many sports require good eye-hand coordination, the ability to engage in multichanneling (Lawson 2001), a good sense of where one’s body is in space, and the ability to track a high-speed object and then perform another task in response (e.g., following a baseball with one’s eye after it leaves the pitcher’s hand and then responding by swinging a baseball bat to hit the approaching ball). The motor coordination nature of many sports conflicts directly with the individual on the spectrum’s disability, thereby discouraging them from participating. Fourth, the social nature of many team sports also discourages participation. Team sports require team members to use both verbal and nonverbal communication where the intent is not always explicit. For example, a

person with an ASD would have to be able to discern the intent of a team member in order to catch a behind-the-back pass or an “alley-oop” in a game of basketball. The person would also have to be flexible and not be too literal in their interpretation of rules of a game in order to be successful and would have to understand concepts like “stealing a base” as being a part of the game and not view it as cheating. The social stressors of team sports may discourage adults with ASDs from engaging in sports and benefiting from exercise. Again, a lack of regular exercise is associated with obesity, diabetes, orthopedic problems, loss of bone density, and heart disease (Pangrazi et al. 2007).

Individual sports may be the best possible solution to the dilemma of the need to exercise through sports. Persons on the autism spectrum could even participate in individual events as a part of a team (e.g., running track and cross country, long jump, or swimming). It would be important to avoid more complex social interactions during these events such as relay races where the stress of attempting to figure out when one is supposed to start one’s leg of a relay can be highly contextualized and requires the reading nonverbal communication.

Swimming has a plethora of benefits as a sport. It is a sport that has low impact upon the joints, and the probability of injury is minimal. Consequently, it is a sport that one can participate in throughout the lifespan. However, for individuals on the autism spectrum, there are additional benefits. For children on the autism spectrum, the number one cause of deaths is accidents. The most frequent accident is drowning followed closely by automobile accidents (Gillberg et al. 2010; Shavelle et al. 2001). By engaging in swimming lessons, individuals on the autism spectrum not only engage in exercise, but they also will learn important survival skills including “drown proofing.” The American Red Cross and YMCAs offer swimming lessons including those adapted for individuals on the spectrum.

As noted previously, many individuals on the spectrum have issues with coordination. Bilateral coordination is particularly poor often with individuals having extreme difficulty doing motions

or actions across their bodies. They frequently have a history of not crawling as infants. Crawling is a complex motor action that involves using alternative halves of the body simultaneously. As infants, this promotes bilateral integration of the brain. In swimming, the crawl (freestyle) or backstroke is one of the few motions that older individuals on the spectrum use alternating halves of the body. While swimming these strokes, the right hand works simultaneously with the left leg, and then the left hand conducts a stroke in coordination with the right leg. This may promote bilateral integration of the brain and improve coordination. The cardiovascular benefits of swimming are well documented.

Walking is an activity that is available to most individuals on the autism spectrum. It requires very little in terms of equipment or training. A sedentary person walks between 1,000 and 3,000 steps a day (www.walking.com). The CDC recommends walking 10,000 steps a day or roughly a little less than 5 miles a day (Besser and Dannenberg 2005). Walking 10,000 steps a day is associated with better cardiac health, reduced stress, better moods, reduced risk of diabetes, lower blood pressure, and improvements in sleep quality (VanBergeijk 2009).

Before starting a pedometer program with individuals on the autism spectrum, an assessment of their skills should be conducted. This includes their knowledge of and ability to implement pedestrian and personal safety. Not only should crossing the street safely be taught, assessed, and reviewed but also the importance of walking with a buddy and not using portable MP3 players set so loudly that they cannot hear oncoming traffic and other dangers. Part of the discussion should also include wearing bright reflective clothing and not wearing hoods that might block peripheral vision. Special care and instruction should be taken around daylight saving time. In the weeks following the change to daylight saving time in the fall, dusk is the most dangerous time for pedestrians. More pedestrians are struck and killed by automobiles at this time than any other time of the year.

When selecting a pedometer, simplicity is the best guide. The more features a pedometer has, the higher the cost will be. More importantly, the

more buttons a pedometer has, the more likely an individual on the spectrum will accidentally reset the device causing possible frustration which can lead to him or her giving up the exercise activity. A simple pedometer with a single reset button and a protective cover is the best option. The device should also have a clip to attach the device to one's belt or waistband and an alligator clip with a tether to avoid losing the device. Some newer-generation MP3 players have pedometers built in as an additional feature to the primary function as a music player.

The pedometers can also be used in combination with persons on the autism spectrum's interest in video games and other pieces of exercise equipment. Wii™ games and Wii Fit™ as well as Dance, Dance, Revolution™ can be used in combination with the pedometers to make exercise fun and engaging. Pedometers can also be used in conjunction with treadmills. They are less effective with elliptical machines and exercise bikes because of the nature of the motion and the manner in which pedometer record movement.

Setting up an incentive and monitoring program will be critical to helping instituting a pedometer program and incorporating walking into a healthy lifestyle. Using behavior modification, individuals should be rewarded for wearing their pedometers and for reaching distance milestones. Graphing the accomplishments and publicly displaying their achievements can instill a healthy sense of competition among participants. Translating the number of steps into mileage and reaching certain well-known geographic landmarks can spur the participants on. Frequent award ceremonies or check-ins are imperative in getting the individuals to incorporate the new behavior into their daily behavior. Incentives should be of interest to the participants, and they should be involved in their selection and the setting of the goals to earn the incentive. If possible, the incentives should also be reinforcing of the activity (e.g., "Million Step Club Member" t-shirts or baseball hats). Challenges and competitions can be issued between subgroups or teams or participants and staff members.

Hiking and backpacking are a natural outgrowth of walking as a form of exercise. Walking

in nature can be a great stress reliever among the peace and quiet of the woods (Rudy 2009) and is considered a perfect sport for children on the autism spectrum (Marinac 2010). The planning of a hike should have a goal of the hiker being able to survive 72 h in the woods in the event he or she becomes lost. Seventy-two hours are the average length of time lost hikers are found by search and rescue teams. Three-quarters of lost hikers requiring search and rescue were simply conducting day hikes with no intention of spending an overnight in the wilderness. Having plenty of water as well as means of extracting and purifying water from natural sources is an essential part of prehike planning. Trail maps, a compass, fire making, and signaling gear are also essential. Orienteering skills should be taught to the individual on the autism spectrum in order for them to be able to navigate and feel a sense of control when in the woods. Hiking can be done as an individual activity, or there are many hiking and conservation groups an individual with an ASD can join where organized trips are planned for the group. If an individual on the spectrum enjoys the outdoors, then kayaking, canoeing, and camping are other recreational activities worth investigating.

Traditional gym memberships are also an option for individuals on the autism spectrum who are interested in maintaining their physical fitness. Many offer running tracks, swimming pools, weight rooms, and organized fitness classes such as yoga, spinning, and cardio classes. For persons with ASDs, it will be important to review social etiquette rules in a gym such as comportment in the locker room, appropriate attire for the various areas of the workout facility, the importance of wiping down the equipment after use, turn taking with the exercise equipment, etc. For those individuals with ASDs who find routine important, gym facilities are excellent environments where they can establish and maintain an exercise routine. Newer-generation gym equipment even combines the use of electronics and computers. Not only can the user watch TV, listen to music, and monitor their speed and heart rates, but they can also play video games as a part of their exercise routine. Some brands of exercise

bikes (both upright and recumbent models) have a video screen where they chase a yellow jersey rider and experience riding in a peloton on a course that the rider selects. Depending on the type of course the rider selects, he or she might be rewarded by seeing a reclusive Yeti or Bigfoot character as a part of the game. With a wireless feature, riders can compete live with other exercise enthusiasts via the World Wide Web (International Fitness Holdings 2011).

If balance and coordination are not issues, then bicycle riding on the street or on a mountain bike trail is another sport that individuals on the autism spectrum could engage in. However, the person's ability to judge traffic and danger should be assessed prior to beginning this activity. Bicycle riding can not only be a great fitness activity but can also alleviate the person's need to rely upon others for transportation. Again, as long as balance is not an issue, then skateboarding or surfing may be considered as a sport for the individual or a form of exercise. With these two activities, protective gear and strong swimming ability are critical.

Martial arts have also been recommended as sports that are excellent for children on the autism spectrum. Among the reported benefits are discipline, increased concentration and memory, better balance and coordination, physical fitness, and increased self-esteem. The repeated practicing of the forms provides the individual with an ASD predictability. The added benefit of martial arts training is that the individual learns self-defense skills. Children with ASDs are often the victims of bullying and as adults are the victims of hate crimes (Sherry 2010).

Horseback riding is a sport that has been proposed not only as a physical fitness activity but as a therapeutic intervention as well. The purported benefits of horseback riding are improved circulation, muscle control, and coordination (Baker 2008). It is also an activity where the participants form bonds with the horses and see the direct benefits of their attempts to communicate with their mounts. A distinction is made between hippotherapy and equine-assisted activities or therapeutic riding. The main differences are who leads the activity and the cost. Hippotherapy is

conducted by a licensed physical or occupational therapist. Consequently, it is considerably more expensive than therapeutic riding which is led by riding instructors. However, some medical insurance may cover hippotherapy (Baker 2008) (see “North American Riding for the Handicapped Association” for a listing of accredited facilities and certified instructors).

The concept of adaptive physical education is one that is derived from the field of special education. Adaptive physical education can be written into a child’s Individualized Education Plan (IEP) under the Individuals with Disabilities Education Act (IDEA). Adaptive physical education is usually taught by someone trained in physical therapy and is used for students who have difficulties with gross motor coordination problems and other types of disabilities who would have difficulty participating in standard physical education classes. Although many individuals on the spectrum have coordination issues, persons with ASDs may benefit from the social skills training aspects of APE. In these classes, the students can be explicitly taught the social rules of team sports and the methods of verbal and nonverbal communication inherent in many games.

A slightly different concept is adaptive physical activity. “Adapted physical activity (APA) is a professional branch of kinesiology/physical education/sport & human movement sciences, which is directed toward persons who require adaptation for participation in the context of physical activity” (International Federation of Adaptive Physical Activity [IFAPA] 2011). Rather than focus upon the therapeutic aspects of working with a population, this approach to sports focuses upon access and adaptation. “In contrast to physical therapies, APA is dedicated to the concepts of empowerment and ecological validity. This means that physical activity of participants is self-driven and targeted towards mastery and excellence” (IFAPA 2011). Although originally this approach evolved from the area of physical disabilities, it is a highly individualized approach that not only involves designing and modifying equipment to maximize participation in a sport but also includes “task criteria (e.g., modifying

skill quality criteria or using a different skill), instructions (e.g., using personal supports, peer tutors, non-verbal instructions, motivational strategies), physical and social environments (e.g., increasing or decreasing court dimensions; segregated vs. inclusive; type of training climate: mastery oriented, collaborative or competitive social environment; degree of peer and parental support), & rules (e.g., double bounce rule in wheelchair tennis)” (IFAPA 2011). The philosophy of this approach is best summarized from its web site: “adapted physical activity is about individualizing instruction, matching personal strengths and interests with appropriate activities and adapting environments to promote full participation in physical activity, regardless of the population being engaged” (IFAPA 2011).

For individuals on the autism spectrum who are truly interested in team sports, the task is to find adaptive physical activities in order to participate in sports as a physical fitness activity. Adaptive leagues are being organized in team sports such as baseball, soccer, bowling, and basketball. A keyword search using “adaptive sports leagues” in an Internet browser can help identify leagues in a local area. If no adaptive leagues are available in the area, then speaking to the organizers and coaches of the local leagues may be a strategy to determine if they have a supportive attitude and philosophy of sportsmanship to include individuals on the autism spectrum.

Adaptive physical activities have been organized for team sports but for high adventure sports as well. This can include skiing, snowboarding, and even scuba diving. With skiing and snowboarding, the individual should be assessed for balance issues, and adaptations should be made accordingly. Prior to scuba diving, participants must be assessed for contraindications to scuba diving which include claustrophobia, asthma, seizure disorder, heart conditions, and potential ear problems. Scuba diving as a sport has, inherent to it, many of the same benefits as swimming but also has additional benefits. Diving teaches participants navigation skills, nonverbal communication, strong reliance on others through the buddy system, emergency management, concentration, and attention to

detail (e.g., time, depth, and air consumption). Some individuals have keen interests in marine biology, and dive trips can be organized around fish and coral identification. Others have interests in history and naval architecture. Nondive time can be spent researching shipwreck sites to explore at a later date on a scuba trip. Many individuals on the autism spectrum are fascinated with computers. The computer can be used not only to research shipwreck sites but other dive sites as well. Dive computers are wrist or console-mounted devices that help a diver keep track of depth, time, and the buildup of nitrogen in the diver's body. Finally, adaptive scuba diving can be the basis for adventure travel for individuals on the autism spectrum (Strayne 2011).

Future Directions

What sport an individual selects to maintain his or her physical fitness is immaterial. What is important is that individuals on the autism spectrum need to participate in 20–30 min of physical activity daily (just like neurotypical individuals) in order to maintain a healthy lifestyle. The risk of obesity and its negative sequelae are higher for individuals on the autism spectrum. Therefore, it is imperative that sports and other forms of exercise become a part of their daily routine. Future research should focus upon what services providers can do to help individuals on the autism spectrum develop a routine where they are engaged in physical activity including sports 20–30 min a day. From an advocacy perspective, the inclusion of individuals on the autism spectrum in sports is an ongoing effort.

Synonyms

Social skills; social emotional skills; social-emotional learning skills

Description

The *Social Skills Improvement System Social-Emotional Learning Edition* (SSIS SEL Edition; Gresham and Elliott 2017) Rating Forms assist professionals in screening and classifying students aged 3–18 years suspected of having significant social emotional learning (SEL) skill deficits. The SSIS Classwide Intervention Program (CIP) is a manualized and fully digitized online treatment programs for improving 23 social emotional skills identified by low frequency ratings on items on one or more Rating Forms. The SSIS uses a multirater (parents, teachers, and students with at least third-grade reading ability) approach that provides a comprehensive

examination of five SEL competency areas (self-awareness, self-management, social awareness, relationship skills, and responsible decision making) and an overall academic competence scale. The instrument is available online or in paper version and yields norm-referenced scores based on a national sample of children representative of the 2006 US Census.

Given that autism is characterized by impaired social interactions, problems with verbal and nonverbal communication, and repetitive/stereotyped behaviors, the SSIS Rating Forms and related CIP intervention manual offer professionals a comprehensive assessment of key SEL skills and an aligned intervention program to specifically address skills identified as relative weaknesses. The SSIS SEL Edition, unlikely the original SSIS Rating Scales (Gresham and Elliott 2008), does not have a separate set of Problem Behavior scales. Thus, autism spectrum disorder (ASD) behaviors are not directly measured on the SEL Edition Rating Forms, but many SEL behaviors commonly targeted for intervention with children with ASD are assessed and aligned with CIP skill units.

Historical Background

The SSiS Rating Scale originally was published in 1990 as the *Social Skills Rating System* (SSRS; Gresham and Elliott 1990). The SSRS was reportedly used by many professionals as part of their autism screening efforts; however, the SSRS was not designed with autism or autism spectrum disorders in mind. When the revision of the SSiS was being conceptualized, the authors consult with educators serving autistic children and the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed., 1994) of the American Psychiatric Association and the National Research Council's report (2001) on *Educating Children with Autism* to ensure they were sensitive to critical identifying behaviors and conditions.

The Collaborative for Academic, Social, and Emotional Learning (CASEL 2013) SEL Framework that features five competency domains

(listed above) inspired the new *SSIS SEL Edition Rating Forms* (SSIS SEL RF) and the *SSIS SEL Edition Screening and Progress Monitoring Scales* (Elliott and Gresham 2017a, b), both published in 2017.

Psychometric Data

The SSIS SEL-RF is comprised of the same 46 social behaviors as the original SSIS Rating Scales, along with five internalizing behaviors (reverse scored). These 51 items, based on a confirmatory factor analysis, represent the five SEL competency domains theorized in the CASEL SEL competency framework. The SSIS SEL Edition Manual provides extensive validity evidence based on test content, internal structure, intercorrelations among scales and subscales, item-total correlations, and relations with other variables (Gresham and Elliott 2017).

Given the restructuring of the SSIS SEL-RF items/scales as compared to the SSIS-RS, modifications of specific subscales prevent direct comparisons; however, total scale internal consistency estimates across forms were comparable between the SSIS SEL-RF and SSIS-RS. Specifically, subscale coefficient alphas on the SSIS SEL-RF ranged from 0.69 (Self-Awareness, Spanish Parent Version) to 0.97 (several subscales across forms), while the lowest alpha for a Composite scale was 0.94. In general, the Self-Awareness subscale yielded slightly lower coefficient alphas than the Self-control subscale, its corresponding subscale on the SSIS-RS. These results are especially apparent on the Parent English and Spanish forms. The internal consistency coefficients for the Responsible Decision Making scale largely equal or exceed those of its related SSIS-RS subscales of Assertion and Responsibility.

A comparison of *teacher ratings* between the SSIS SEL-RF and SSIS-RS forms revealed high levels of agreement across composite and subscale scores ($p < 0.05$). The SSIS SEL-RF Composite ($r = 0.98$) and Core Skills ($r = 0.92$) scales strongly correlated with the SSIS-RS Social Skills scale and demonstrated moderate to high

correlations with the corresponding subscales. Furthermore, significant negative relationships were revealed between teacher ratings on the SSIS SEL Composite and Core Skills scores with the SSIS-RS Problem Behaviors scale and subscale scores, providing evidence for divergent validity of the negative relationship between social emotional skills and problem behaviors.

Similar to the comparisons of teacher ratings, *parent ratings* on the SEL composite scale, Core Skill scale, and related subscales yielded high correlations across the SSIS-RS Social Skills scale and subscales ($p < 0.05$). Concerning divergent validity, all SSIS SEL-RF parent ratings negatively correlated with the SSIS-RS Problem Behavior composite scale and subscales, providing further evidence for differences between positive social and emotional skills as measured by the SSIS SEL and problem behaviors.

Correlations between student ratings on the SSIS SEL-RF and SSIS-RS also revealed strong positive relationships between all composite scales and subscales ($p < 0.05$). These results provide support for the convergent validity between the two forms. Furthermore, ratings between the SSIS SEL-RF skills and the SSIS-RS Problem Behavior composite scale and subscales demonstrated strong negative relationships, presenting additional evidence for divergent validity. An exception to these results was the Internalizing subscale on the SSIS-RS, which did not produce any correlations higher than 0.18 with the SSIS SEL-RF scales. Additionally, the relationship between Social Awareness and Hyperactivity/Impulsivity ratings was also weak ($r = 0.16$).

Correlations between the SSIS-RS and SSIS SEL Edition with the *Behavioral Assessment System for Children*, Second Edition (BASC-2; Reynolds and Kamphaus 2004) are moderate to high, depending on the scales and subscales. Correlations between the SSIS-RF total social skills scores and the socialization scores of the *Vineland Adaptive Behavior Scales*, Second Edition (Vineland II; Sparrow et al. 2005) are also moderate to high for the teacher and parent forms, respectively.

Using a sample of 50 students with an autism spectrum disorder as diagnosed by the DSM-IV-TR, a known group comparison analysis with a nonclinical sample was conducted. On the Teacher and Parent forms of the SSIS, all the mean score differences were statistically significant. The SEL scale means at least 1.5 standard deviations lower than the nonclinical reference sample of students. These results are consistent with expectations that individuals with autism spectrum disorder have major deficiencies in social emotional skills. Thus, lending substantial support for the validity of the scores of this subscale as a measure of behaviors typically exhibited by individuals diagnosed with autism.

Clinical Uses

The SSIS Rating Forms, comprised of the Teacher, Parent, and Student rating forms, are intended to be used as comprehensive measures of children's social emotional skills. In particular, these rating scales are designed to identify social emotional skill acquisition and performance deficits in areas of self-awareness, self-management, social awareness, relationship skills, and responsible decision making. By using the nationally representative norming sample for comparison, it is possible to get a clear comparison between a student suspected of an autism spectrum disorder to a same age and sex comparison group of non-clinical students. The assessment results can be used to identify specific skill deficits that link directly to SSIS CIP intervention skill units, where SEL skills are directly taught via a manualized treatment supported with rich online resources designed to engage students in the process of skill development and generalization.

Stalking

Laurie A. Sperry¹ and Mark A. Stokes²

¹Department of Psychiatry, School of Medicine, Yale University, New Haven, CT, USA

²School of Psychology, Deakin University, Burwood, VIC, Australia

Definition

Stalking, also referred to in the extant literature as obsessional following, obsessional harassment, and obsessive relational intrusion (Meloy 2001; Rosenfeld and Harmon 2002; Spitzberg and Cupach 2007), consists of a continuum of behaviors involving harassment and threats over time that serve no purpose other than to cause fear in the victim and distress over their safety (Sheridan and Davies 2004).

Historical Background

The Stalking Risk Profile (MacKenzie et al. 2012) categorizes typologies of stalking representing various motivations and precipitating factors.

Rejected stalking results from the dissolution of a close relationship such as former intimate partners. Often the rejected stalker is trying to repair the relationship and with it their sense of self-worth but when this proves fruitless, revenge may be the focus of their behavior.

Resentful stalking occurs when the stalker perceives they have been disrespected, humiliated, or have received unfair treatment. The victims may or may not know the perpetrator but are perceived to have committed the slight or injustice. The genesis of this type of stalking is revenge which can be maintained by the power they feel through demonstrations of the victims' fear. When this type of stalking is directed to an organization, the stalker may feel like they are standing up for themselves against the oppressors.

Predatory stalking typically involves male perpetrators and female victims unknown to the perpetrator but with whom he has developed a

sexual interest. The behaviors can range from voyeurism resulting in sexual gratification to using the stalking as a means of amassing information with the ultimate goal of sexual assault.

Intimacy-seeking stalking results from social isolation and a dearth of emotionally/physically intimate relationships. Intimacy seekers often target a stranger, celebrity, or casual acquaintance and develop delusional beliefs that they are having a relationship with their victim.

Similar to the intimacy seeker, **the incompetent suitor** operates from a position of loneliness though their motivations may be primarily focused on establishing sexual intimacy. The duration of their stalking is typically less than other typologies and is characterized by a mindblindness to the anguish of their victims. This lack of perspective taking is often associated with perpetrators with autism spectrum disorder (ASD).

For the purpose of this chapter, we will focus on **the incompetent suitor** typology and attempt to explain how the characteristics of ASD, in particular social challenges, perspective taking, circumscribed interests, and a strong need for routines and rituals, may be implicated in the commission of a stalking offense.

Current Knowledge

Risk Factors

Desire Versus Skillset to Initiate and Maintain Intimate Relationships

Contrary to popular belief, many people with ASD desire intimate relationships. However, in assessments of their knowledge of sexuality, they score below their typical peers in all areas except body part identification and knowledge of menstruation (McCabe and Cummins 1996). They often have a paucity of vocabulary to describe relationships or identify what makes someone an appropriate target for a romantic relationship. Moreover, for a group of people who have often been the targets of bullying and harassment (Little 2002), small gestures of kindness may be interpreted as romantic overtures. When

asked what makes someone your girlfriend, a man with ASD serving a lengthy prison sentence for stalking reported “You just know.” When plumbed for further information he reported, “She was nice to me.” This juxtaposition of the desire for intimacy with the challenges in understanding what constitutes an intimate relationship may lead to trouble and even criminal charges.

Victim as Circumscribed Interest

Evidence would suggest that the majority of individuals with ASD have circumscribed interests, manifested as part of their experience of their ASD (Klin et al. 2007), and that these circumscribed interests occupy their attention longer and will prevent exploration of other pursuits (Sasson et al. 2008). It has been found that circumscribed interests may become more intense for those with ASD (Anthony et al. 2013) or involve greater emotional attraction (Sasson et al. 2012) than interests do for typically developing (TD) individuals.

As individuals with ASD approach adolescence, they manifest desire to have normal sexual and romantic relations (Dewinter et al. 2015; Stokes and Kaur 2005), and yet, while normal sexual experiences can occur (Dewinter et al. 2015; Ginevra et al. 2015), compared to TD individuals, those with ASD more frequently fail to obtain lasting relationships (Dewinter et al. 2017; Stokes et al. 2007). Moreover, as a group these individuals have reduced sexual knowledge (Ginerva et al. 2016; Stokes and Kaur 2005), which has been associated with sexual offending among a minority of this group (Baarsma et al. 2016).

Few studies have examined offending behaviors, let alone stalking, among those with ASD. One, Stokes et al. (2007), examined 25 individuals with ASD found that this group reported a willingness to pursue strangers, ex partners (where they had these), and celebrities considerably more so than TD individuals and that they would pursue the victim longer if the rejection of this was made explicit. Indeed, individuals with ASD are noted for perseveration in the face of error (cf. Landry and Al-Taie 2016). This is akin to persisting and trying again using the same failed

strategy as was first used seeking the possibility that with practice it may work. Broadbent and Stokes (2013) explored whether the unwanted pursuit might be perversely encouraged by active rejection. They undertook a modified Wisconsin Card Sort Task with 50 individuals with high functioning ASD and 50 TD individuals, where in one condition negative reinforcement was removed. It was found that negative reinforcement trapped individuals with ASD, so that instead of modifying their strategies, those with ASD persisted longer in the face of negative reinforcement yet performed significantly better when offered only positive reinforcement for correct choices. These results suggest the victim may become a circumscribed interest for those with an ASD. Fortunately, recently published results suggest that individuals with ASD can learn strategies to reduce their inappropriate behavior and focus upon a person (Dekker et al. 2015).

Stalking as the Routine/Ritual

People with ASD often have a strong need for routines and rituals (Bishop et al. 2013). When a routine or ritual is disrupted, they often have a need to restart the ritual from the beginning. The daily calls, obsessional following, gift giving, showing up at the victim's place of employment, and other behaviors that constitute obsessional harassment may have become part of the person's routine. This completist mentality, "I have to start from the beginning until I get it right," may lead to criminal stalking, probation or parole violations relative to restraining orders, or even instances of recidivism.

Difficulties with Perspective Taking

Ironically, stalking is largely predicated on the perception of the victim (Ngo and Paternoster 2016) and, however, may be perpetrated due to lack of perspective taking on the part of the person with ASD. From the perspective of the victim, they may think they are simply being kind to a person who appears to have few friends while the person with ASD may assume that this is a romantic gesture. Faced with increasingly uncomfortable attention, the victim may begin to ignore the person, thinking they will leave them alone. This

can be interpreted by the person with ASD as a need to work harder to "win the person back." The victim may then believe that if they speak to the person one more time, and explain themselves, they will be left alone. Unwittingly, they have engaged in intermittent reinforcement of the problem behavior (stalking), which builds the most durable behaviors (Skinner 1954; Broadbent and Stokes 2013). The person with ASD is now faced with a lack of access to their romantic target so they may begin to seek out other places to see the person. This escalation could take the form of driving down the person's street, walking past their home, and showing up at their place of work. Both parties may arrive at the same emotional state when the police are called – terrified and wondering why this is happening to them.

Time Spent Online

People with ASD spend an inordinate amount of time online relative to the time they spend pursuing other leisure activities (Mazurek and Wenstrup 2013). Cyberstalking in the form of obsessional following and harassment may result from the person's proclivity toward online activities and the ease with which they can access personal information about their intended target. Moreover, cyberstalking may be easier than off-line stalking as it can be done from a home location and does involve the degree or social interaction, transportation, or community access skills required for off-line stalking.

Media Influences

The media's influence on romantic knowledge is important. Many individuals consume a considerable amount of media (Nielsen 2014), and it has been found that individuals with ASD consume more (Mazurek and Wenstrup 2013) and are less discerning of this than are TD individuals (Kuo et al. 2015). Those with ASD have been found to be 2.3 times more likely to learn their romantic knowledge from the media than were TD individuals (Stokes et al. 2007). If this source of learning was the entirety of this issue, it would be simple to address. However, part of the trouble is that individuals with ASD tend to take things at face value, misinterpreting the kindness of others as

indicating romantic interest (Attwood 2007). Viewers without autism likely recognize the hyperbole in the popular media when it comes to the glorification of stalking characterized by romantic tenacity that results in obtaining the affections of the object of their desire (Spitzberg and Cadiz 2002). Media images, taken at face value, may become a script, albeit inappropriate, that the person with ASD utilizes in their romantic pursuits believing that this behavior will result in garnering the attention of their intimate target. It is considered likely that impaired theory of mind function may contribute to this phenomenon. It is unsurprising that this misinterpretation will lead to rejection, and while the majority of individuals with ASD do not involve themselves in vengeful violence against others for this rejection, violent vengeful sexual fantasies have been reported in a small number of individuals with ASD (Palermo and Bogaerts 2015). More generally, those with ASD may utilize strategies to initiate romantic contact that would be unusual in their intensity compared to that undertaken by TD individuals. These may include touching, pursuing, and the making of threats (Stokes et al. 2007). The consequence is that the target person may reasonably seek to inform their pursuer that they are not interested, and this then leads the individuals with ASD to become trapped into trying harder to improve their technique in the forlorn hope that their target will recognize the suitability of them as a partner (Broadbent and Stokes 2013).

Future Directions

Individuals with ASD need greater and fuller understanding of how to interact in the complex world of human relationships. It would be ideal to suggest that the TD world could adjust itself to better accommodate those with ASD. However, this is unlikely. Interpreting others' intentions in romantic relationships is fraught with error among TD individuals (de Quadros-Wander and Stokes 2007); it is unlikely that the TD population will modify their evolutionarily derived behaviors to accommodate those with ASD. Therefore, changes in understanding are required among

those with ASD. To this end Dekker et al. (2015) have evolved a promising program of cognitive interventions that appears to assist those with ASD to adjust their thinking and behavior. Additionally, to date, the extent to which romantic rejection is associated with well-being failure in those with ASD has yet to be elucidated, as has their responses to this. Unfortunately, individuals with ASD typically do not receive this type of education until after they have engaged in a behavior that has reached the level of criminality (Griffiths et al. 2002). They may not be aware of the illegality of their behavior nor are they aware of the consequences. Proactive intimacy education should be specifically focused on increasing their understanding of relationship vocabulary and identification of appropriate targets for romantic pursuits, with a focus on developing appropriate replacement behaviors when rejection does occur (Gerhardt 2009). Targeted skill development can provide individuals with ASD with the necessary social tools to pursue the intimate relationships they so often desire.

Standard Deviation (SD)

Justin Rowberry
Developmental and Behavioral Pediatrics, New Haven, CT, USA

Definition

The standard deviation is a measurement of the amount of variance a data set has from its mean. The larger the standard deviation the greater the variance; the smaller the standard deviation the less variance exists. The standard deviation is represented by the Greek letter sigma σ .

The standard deviation is calculated by finding the square root of the variance or, in other words, finding the square root of the average of the squared deviations of each number from the mean of all the numbers.

Standard Error of Measurement

- [Measurement Error](#)

Standard Error of the Mean

Domenic V. Cicchetti
Departments of Psychiatry and Biometry, Yale Child Study Center, Yale University, New Haven, CT, USA

Definition

Standard Error of the Mean refers to the error associated with estimating a mean or average score of a population, or a sample (N), where N refers to the Number of subjects.

It is defined mathematically as the standard deviation (S.D.) divided by the square root of N . The logic behind this simple formula is evidenced by the quick realization that the larger N becomes, the smaller the absolute error in estimating the true or population mean.

This same logic is used in polling undertaken in political races. When pollsters claim that the margin of error is, say, plus or minus three points and one candidate shows a lead of only 2% points, they say further that such a result must be interpreted with caution because it is “within the margin of error.” The margin of error is, in turn, based upon the size of the standard error of the mean, such that the larger the standard error, the less accurate the polling results, and vice versa.

Let us now take an example of the usefulness of knowing the standard error of the mean in understanding a hypothetical level of clinician agreement in diagnosing a given child as one of the following: non-autistic; on the autism spectrum, but not meeting full criteria for autism; or meeting current DSM criteria for autism. Suppose that using the Weighted Kappa statistic (Cohen 1968), with the corrected standard error due to Cicchetti and Fleiss (1977) and Fleiss et al. (1969), we discover the following: The overall Percentage of Observed (PO) agreement for our two well-trained clinicians is 94%. Suppose further that the Percentage of Expected (PE) agreement turns out to be 60%. Weighted Kappa is defined as the difference between observed and expected agreement (PO – PE) divided by the maximum difference from expected agreement that is possible (100 – PE).

This translates into : Weighted Kappa–

$$\begin{aligned} &= (\text{PO} - \text{PE}) / (100 - \text{PE}) \\ &= (94 - 60) / (100 - 60) \\ &= .85 \end{aligned}$$

The level of statistical significance of a given Weighted Kappa value is determined by dividing the size of Weighted Kappa by its Standard error of the mean (S.E.). This produces a *z* score such that a value of 1.96 or higher is statistically significant at the .05 level of probability. Suppose our S.E. based upon 250 cases is .425. This produces a *z* of 2.00, which is indeed significant at the .05 level.

But how do we interpret the Weighted Kappa value of .85, for level of clinical or practical significance?

By the criteria of Cicchetti (1994), Cicchetti and Sparrow (1981), and Fleiss et al. (2003), the Weighted Kappa value can be considered Excellent, and by the earlier criteria of Landis and Koch (1977), a Weighted Kappa value of .85 can be considered to be almost perfect.

Standard Scores (Z and T Scores)

Domenic V. Cicchetti

Departments of Psychiatry and Biometry, Yale
Child Study Center, Yale University, New Haven,
CT, USA

Definition

Standard Scores are raw scores that, for ease of interpretation, are converted to a common scale of measurement, or z distribution, with a mean or average value of 0 and a standard deviation of 1. When sample sizes, or *N*s, are small, say less than 200, standard scores are interpreted as t scores. The simple formula for calculating a z score is: $Z = (X - \bar{X}) / S.D.$ in which: *X* = the aforementioned raw score $\bar{X}$ = the converted average or mean score of the population under investigation *S.D.* = the standard deviation of that population When the sample size is large, a z value of + or -1.96 so-called standard deviation units is statistically significant at the conventional 5% level of statistical significance. Thus, if the difference in average adaptive behavior scores of a large group of Asperger individuals and a large group of high functioning autistic persons resulted in a z value of 2.06, we would conclude, correctly, that the high functioning group had significantly higher overall adaptive behavior scores. However, if we now inspected the average scores of the two groups and discovered that they were standard scores of 104 and 100, respectively, we would likely conclude that although the difference was statistically significant, it was of limited clinical or practical significance. One should note that in the interpretation of the meaning of IQ score levels, scores are not based upon a mean or average of 0 and a standard deviation of 1; but rather -again for ease of interpretation- upon a mean of 100 (average IQ) and a standard deviation of 15. This is true for most, but not all major

IQ tests. As an application, suppose we find in another large-sample study that Asperger individuals have an average IQ of 125 as compared to the average IQ of 100 in a group of non-Asperger general population individuals; and that this was statistically significant, say, at the 1% level. The difference in the size of the two mean IQ levels would be seen to be of clinical or practical significance, as well. It has been noted that a sample size of 200 is considered large; in fact, this is often used by biostatisticians to define a large *N*. This is no doubt related to the simple fact that as *N* gets larger, the t distribution values closer and closer approximate the z distribution values. For example, at an *N* of 120, a t value of 1.98 would be required for statistical significance at the 5% level. Thus a sample size or *N* of 200 virtually guarantees the required z level of 1.96.

Standardization

Domenic V. Cicchetti

Departments of Psychiatry and Biometry, Yale
Child Study Center, Yale University, New Haven,
CT, USA

Introduction and Definition

Standardization is the process by which a test is administered in a standard or uniform manner from one examinee to another, as well as from one testing milieu to another. This means the test uses a consistent set of rules or instructions to obtain performance scores that should be conceptually more reliable and valid (accurate) than

would be the case if the test were administered in what might be referred to as changing or variable test administration formats – ones that could vary from one test administrator to another, and from one respondent, client, or examinee to another.

Standardization Sample

It is safe to say that the most useful standardization sample would be a large and representative one in the country or other geographic area in which the process takes place.

Standard Scores

Standard scores have exactly the same format, meaning, and interpretation as *z* scores. These scores are based upon a mean or average score of 0 and a standard deviation of 1. A score of 0 would indicate the mean or average score; while one of +1.96 would indicate a score that would be expected to be obtained by only 5% of respondents.

The same logic is used with standard test scores. Most standardized tests such as the Vineland Adaptive Behavior Scales and most cognitive or IQ tests are based upon an average or mean score of 100, with a standard deviation of 15. By the same reasoning as was done for the aforementioned *z* score, this would mean that only 5% of those taking either one of these two tests would be expected to score as high as 115 (again, one standard deviation above the mean or average score of 100).

Interpreting the Meaning of Standard Scores, with Reference to Vineland II Adaptive Behavior Scores

The possible range of Vineland Composite or Domain scores is between more than five standard deviations *below* the mean (or a standard score of

20) to four standard scores *above* the mean (or a score of 160) (Sparrow et al. 2005).

Classifying Levels of Adaptive Behavior on the Basis of a Knowledge of Standard Scores

As noted in Sparrow et al. (2005, p. 65), Vineland Adaptive Levels, like scores on most IQ tests, can be meaningfully classified on the basis of the size of the associated standard score. This can be illustrated, as follows:

Adaptive level	Standard Score Range
High	130 and above
Moderately high	115–129
Adequate	86–114
Moderately low	71–85
Low	70 and below

How Standardized Test Scores Can Be Used to Understand Autistic Behavior

It is expected that a typical pattern of functioning for a person with Asperger Syndrome would be a relatively high IQ score, with a correspondingly relatively low Vineland Socialization standard score. Thus, it would not be unusual for such an individual to have an IQ score of, say, 125 in the moderately high range; but a socialization standard score of 80, or in the moderately low range. In developing an educational plan, emphasis would be mainly on developing and applying techniques to improve interpersonal skills, since cognitive skills are at a very adequate level of functioning.

Synonyms

[Rating scale](#); [Report form](#)

Definition

A list of behaviors used to characterize an individual. Checklists can be self-rated, but in the ASD field they are most often completed by informants who know the person well, such as parents, teachers, workshop supervisors, or support staff. Both the items and the response categories are *standardized*, meaning that all users respond to the same questions on the same scale. Often this response scale will be *Likert*-style, which means that responses are ordered along some dimension (e.g., *strongly agree*, *agree*, *neutral*, *disagree*, and *strongly disagree*). Responses are then scored in a standard manner, meaning that it is possible to compare the results across individuals or groups of individuals. Scores may be compared to reference samples, called *normative data*, to determine whether the individual's behavior is similar to his or her peers ("peers" may be defined by any number of characteristics, but usually refers to chronological age and, sometimes, sex). A high-quality standardized checklist will be empirically derived, using standard scale development techniques (e.g., *factor analysis*, *item response theory*), and will have well-established psychometric properties (e.g., *acceptable*, *reliability*, *validity*).

Standardized behavior checklists are used for individuals with autism, both in clinical and

research contexts. Checklist scores are not sufficient for a formal diagnosis of any disorder but may be used by the clinician to inform the diagnostic process. For example, a child's scores on the *Child Behavior Checklist*, the most commonly used standardized behavior checklist in child psychiatry, may be used by the clinician to screen for the presence of externalizing or internalizing disorders. Because checklists are usually faster to administer and less expensive than interview- or observation-based assessments, they are used frequently as outcomes in research. For example, scores on the *Aberrant Behavior Checklist* are often used to evaluate the effectiveness of medication intervention on problem behaviors in children with autism.

[Scales;](#) [Stanford-Binet Intelligence Test](#)

Description

The Stanford-Binet Intelligence Scales – Fifth Edition (SB5) – is a widely used individually administered measure of intelligence and cognitive abilities for children and adults ages 2 to 85+. Average testing time is 45–75 min to complete the full-scale IQ battery. An Abbreviated Battery IQ

is available which takes 15–20 min to complete but provides a more restricted assessment of cognitive abilities. The nonverbal IQ domain which can be administered to individuals with limited language abilities, and the verbal IQ domain, which can be administered to individuals with motor and visual impairments, take approximately 30 min each to administer.

The SB5 provides a comprehensive assessment of five factors of cognitive ability: fluid reasoning (ability to solve nonverbal and verbal problems using reasoning skills), knowledge (fund of general information), quantitative processing (ability to work with numbers and solve numerical problems), visual-spatial processing (ability to see patterns, relationships, and spatial orientations), and working memory (ability to store, sort, and transform information in short-term memory), which provide a profile of differential abilities. The SB5 also contains two domain composites: nonverbal IQ (NVIQ) and verbal IQ (VIQ). The five factors are crossed with the two domains resulting in ten subtests. The five factor indexes or the two domains can combine to form the full-scale IQ (FSIQ).

The SB5 has two subtests known as “the routing subtests” which are administered at the beginning of the test to help determine an initial estimate of the examinee’s abilities and to identify an appropriate developmental starting point for the remaining subtests. The nonverbal fluid reasoning subtest (object series and matrices) provides an overview of an examinee’s nonverbal ability, while the verbal knowledge subtest (vocabulary) is an indicator of an examinee’s verbal ability. Excluding “the routing subtests,” items for all subtests are grouped into “testlets” which are arranged by five levels of difficulty for the verbal domain and six levels of difficulty for the nonverbal domain. Many of the SB5 subtests contain more than one item due to the wide range of ages and abilities that each subtest covers. During the administration of the SB5, individuals are administered a series of testlets at each level of functional ability. According to the author, the assessment of several domains in each functional level provides a broader assessment and a larger variety of tasks to maintain the examinee’s interest. Some subtests are

also comprised of different types of “activities” which do not specifically conform to testlets. Activities may extend across several testlets with different levels of difficulty. The SB5 is organized into three item books, one for the routing subtests, one for the verbal subtests, and one for the nonverbal subtests.

The SB5 generates a standard score ($M = 100$) with a standard deviation of 15, which is different than previous versions which had a standard deviation of 16. Subtest scores have a mean of 10 and a standard deviation of 3. The full-scale IQ of the SB5 ranges from 40 to 160.

Historical Background

The SB5 is the newest version of this well-established intelligence assessment that has a long-standing and rich history. The Stanford-Binet is a descendant of the first intelligence test, the 1905 Binet scale. In 1916, Lewis Terman completed an American version of the Binet-Simon Intelligence Scale (SB1). The test was then revised in 1937 (SB2) and renormed in 1960 (Stanford-Binet Intelligence Scale, Form L-M). It was revised again in 1986, resulting in the Stanford-Binet Intelligence Scale – Fourth Edition (SB-IV). The earliest version of the test used item groupings to assess functional ability, which were arranged by levels based on order of difficulty. The 1986 version, SB-IV, changed to a subtest-based point system based on items of increasing difficulty, much like other intelligences tests such as the Wechsler scales. The SB-IV also addressed theories of g measuring crystallized and fluid abilities. The following is a summary of the new features of the fifth edition (Roid 2003b; Strauss et al. 2006):

(a) Expansion of the test to allow the assessment of very low and very high levels of cognitive ability (i.e., extensive high-end items for measuring the highest level of gifted performance and improved low-end items for better measurement of young children, low functioning older children, or adults with mental retardation)

- (b) Restoration of the original toys and manipulatives for assessing preschoolers that had been removed from previous versions
- (c) Increased clinical utility
- (d) Updated materials
- (e) Increased nonverbal items to assist with assessment of examinees with limited English, deafness, or communication disorders
- (f) Increased range of domains measured by the test
- (g) Enhanced memory tasks to provide a comprehensive assessment for adults and the elderly
- (h) Ability to compare verbal and nonverbal performance to assist with evaluating learning disabilities

As a result of these goals and changes, several new subtests were added, but many of the classic subtests were maintained. While the SB-IV measured four factors (verbal, quantitative, abstract/visual reasoning, and short-term memory), the SB5 measures five factors (fluid reasoning, knowledge, quantitative reasoning, visual-spatial processing, and working memory). These factors are based on Cattell-Horn-Carroll theories of intelligence which posits that there are ten broad areas of cognitive ability with narrower abilities underlying these broad factors. Factors that are not measured by the SB5 are auditory processing, long-term retrieval, and processing speed. The SB5 maintained the “routing” subtest technique which was developed in the 1986 version and continues to present items according to function levels. For the SB5, both the routing subtests and functional levels were redesigned using current psychometric methods including item response theory.

Psychometric Data

Normative data for the SB5 were gathered from 4800 individuals between the ages of 2 and 85+ and was closely matched to the 2000 US Census based on age, gender, race/ethnicity, geographic region, and socioeconomic level. The SB5 was also administered to 1365 individuals with mental health and clinical diagnoses (e.g., ADHD,

autism, developmental disability, motor impairment, mental retardation, speech/language impairment, deafness/hard of hearing, and emotional disturbance).

Internal reliability is strong for the full-scale IQ at all ages ($r = .97-.98$). Reliabilities for the nonverbal IQ and verbal IQ are also very high (mean $r = .95$ and $.96$). The Abbreviated Battery IQ is lower but still good (mean $r = .91$, range $.85-.96$). Average reliabilities for the five factor index scores are high ($r = .90-.92$). The average internal consistencies are also respectable ($r = .84$ to $.89$). Overall, test-retest reliability is also good. (Four groups were retested after a test interval of 5–8 days; see Technical Manual.) Full-scale IQ and verbal IQ stability was high for all ages ($r = .93-.95$). Nonverbal IQ was slightly lower ($r = .89-.93$). Abbreviated Battery IQ was also lower but still acceptable ($r = .84-.87$). Subtest and factor index test-retest reliability was generally good ($>.80$); however, the Working Memory Index only obtained adequate reliability in adults. Practice effects were also evaluated and considered to be minimal after a 5–8-day interval. The full-scale IQ increased two to four points, the verbal IQ increased two to three points, and the nonverbal IQ increased two to five points.

Content validity for the SB5 is based on 7 years of development which included literature review, expert advice, user surveys, factor analyses of previous versions, pilot studies, tryout edition, and item response theory modeling. Fairness of the SB5 was evaluated along gender, ethnic, racial, cultural, linguistic, exceptional group status, and religious group status. Fairness evaluation techniques included logical analyses, “offensiveness review” by expert bias reviewers from each of the groups, and various empirical techniques such as conventional item analysis, construct-related studies, and studies of fairness prediction. Based on these evaluations, the SB5 is considered a fair test across groups. Concurrent and criterion validity data were obtained using the following tests: Stanford-Binet Intelligence Scale, Fourth Edition; Stanford-Binet Form L-M; Woodcock-Johnson III; Universal Nonverbal

Intelligence Test; WAIS-III; WIAT-II; WISC-III; and WPPSI-R.

Clinical Uses

The SB5 has a wide variety of uses but is generally considered to be a measure of intelligence and verbal and nonverbal cognitive abilities. SB5 scales are used in the diagnosis of conditions such as intellectual disability (all ages), learning disabilities (all ages), and developmental cognitive delays in young children. It can also be helpful in the assessment of students in programs for the intellectually gifted. Supplemental assessments are usually administered along with the SB5 to assist with assessment and diagnosis. The fifth edition of the SB is designed to provide information for interventions including individual family plans (IEPs) for young children, support from school-to-work transition planning, adolescent and adult career change, employee selection and classification, and adult workers compensation evaluations. The SB5 may also be useful in forensic contexts, as well as part of research assessment batteries investigating abilities and aptitudes. The SB5 does not measure processing speed, an important factor in the assessment of neuropsychological conditions, and therefore, the SB5 may need to be supplemented by other neuropsychological tests to assist with differential diagnoses. Clinical data on patients with traumatic brain injury and Alzheimer’s is also lacking to date. The SB5 is typically administered by psychologists or trained psychometrists with supervision by a psychologist in clinical, counseling, school, or research settings. As with many psychological assessments, the overall usefulness of the SB5 is strengthened when combined with other appropriate assessments to give a well-rounded picture of the examinee.

STAR Program

Elizabeth Schoen Simmons
Department of Psychological Sciences,
University of Connecticut, Storrs, CT, USA

Definition

The STAR (Strategies for Teaching based on Autism Research) Autism Program uses applied behavior analysis methods to teach skills in the areas of expressive and receptive language, spontaneous language production, functional routines, academic skills, play, and social interaction to children with ASD. It combines the highly structured teaching approach of discrete trial training with a more naturalistic-based approach of pivotal response teaching. Its curriculum was designed to be implemented by a variety of professionals such as special educators and speech-language pathologists, as well as by paraprofessional support staff. The STAR program has three different curriculum modules chosen based on the child's current level of functioning. However, limited empirical evidence is available to support the efficacy of this program.

Historical Background

The STAR program is based on the work of Drs. Joel Arick and David Krug, who initially developed a program combining several behavioral strategies for teaching children with autism including discrete trial training, augmentative communication systems, and the teaching of independence skills. This program was utilized in local school systems. Subsequently, they published a book entitled, *Autistic and Severely Handicapped in the Classroom: Assessment, Behavior Management and Communication Training*, describing the curriculum (Krug et al. 1981). In the late 1990s, Drs. Arick and Krug began a collaboration with

Dr. Ruth Falco and Lauren Loos. This collaboration functioned to help develop a program driven by empirically based teaching methods.

Rationale or Underlying Theory

The purpose of this program is to use research-supported strategies to teach children with autism basic skills including language, pre-academic, social skills, and functional routines. There is a highly structured discrete trial component to teach skills initially, and then a less structured, naturalistic approach is used in an attempt to generalize those skills.

Goals and Objectives

This manualized program includes three levels, each with learning goals in the areas of language, social development, academic skills, and functional routines. Each child begins the program at the level that is congruent with their current developmental skill set.

Treatment Procedures

Skills are initially taught in a discrete trial format in a 1:1 instructional setting and data are collected. Once the skill is mastered, the skill is then taught in a more naturalistic context using a pivotal response teaching method. The second edition of this manualized program is now available and includes multimedia materials.

Efficacy Information

Limited empirical evidence is available to support the efficacy of this program. While there is evidence that supports the techniques used in this treatment approach, the program as a whole has limited data to support its efficacy.

Outcome Measurement

Arick et al. (2004) developed the Functional Assessment and Curriculum for Teaching Everyday Routines as a measure of a student's ability to participate in classroom activities.

Qualifications of Treatment Providers

Unlike many treatment programs for children on the autism spectrum that require implementation by a Board Certified Behavior Analyst, this program is designed to be implemented by a variety of individuals including teachers, support staff, and caregivers.

Startle Reflex

Lindsey Sterling

Department of Psychiatry, Jane and Terry Semel
Institute for Neuroscience and Human Behavior
UCLA, Los Angeles, CA, USA

Synonyms

[Startle response](#)

Definition

A species-specific automatic response to the sudden onset of an acoustic, visual, or tactile stimulus. This response, or reflex, is viewed as a defensive response that varies systematically with the individual's emotional state. The startle response is characterized by a fast series of muscle contractions around the head, neck, and shoulders; the sudden closure of the eyelid (i.e., eyeblink) is the first, fastest, and most reliable component of this reflexive response. The startle reflex is mediated in part by the amygdala. Strength and latency of startle reflex, or eyeblink, have been used to investigate amygdala function in various psychiatric populations with putative amygdala dysfunction (e.g., autism, anxiety).

State Educational Agency

Jacqueline Kelleher

Education, Sacred Heart University Isabelle
Farrington School of Education, Southern
Connecticut State University, Fairfield, CT, USA

Definition

The state education agency (SEA) refers to the state board of education or other agency or officer with the primary responsibilities for oversight and supervision of public elementary and secondary schools. In cases where there is no state board or agency with the authority to conduct supervision over local education agencies (LEAs), the SEA defaults to the officer or agency designated by the governor or in state law.

Statewide Service Programs

Peter Doehring
Foundations Behavioral Health, Doylestown,
PA, USA
ASD Roadmap, Chadds Ford, PA, USA

Definition

Definition: Integrated programs that are explicitly structured to provide, or to directly facilitate the provision of, services to a population of persons with ASD across an entire state. Statewide programs that provide services directly to clients with ASD using a relatively uniform standard of practice are very rare, and so for purposes of comparison we also describe below examples of programs that are formally mandated, designed, and/or contracted to provide *training* to service providers in a specific approach related to ASD treatment and/or education across an entire state (e.g., statewide networks for training in positive behavior supports).

For purposes of this definition, we would only consider programs formally mandated, designed, and/or contracted to provide services across a state to be truly statewide. Private, regional centers may offer excellent services across a region but, absent a formal mandate, we cannot expect them to ensure reasonable access to these services to all residents of a state.

We have also only considered programs established in the United States. Whereas many developed nations have a regional layer of service organization (e.g., départements in France, provinces in Canada, etc.), descriptions of variations from country to country in the organization of this layer are beyond the scope of this entry. Nonetheless, the range of opportunities and challenges offered by statewide service programs in the United States is likely to be comparable to those apparent elsewhere (Doehring and Becker-Cottrill [in preparation](#)).

Historical Background

As part of the broader national trend in the United States between 1890 and 1930, many states developed specialized centers for specific populations that (it was believed) could not be easily accommodated in society: for example, state psychiatric hospitals, state schools for the deaf and for the blind, etc. The development of these centers coincided with the increasingly prominent role of the state in health and education, and was spurred by advances in treatment. Some of these centers grew to be very large, serving thousands of patients who often resided there for much of their lives. With the rise of the disabilities rights movement, the passage of Public Law 94–142, and the move toward deinstitutionalization beginning in the mid-1970s, many states moved away from a reliance on large, stand-alone centers to the development of multisite, community-based programs.

Throughout much of this period, autism remained too rare a disorder to merit its own specialized statewide centers, and we believe that this had a significant impact on the quality of services available. Moreover, because the needs of persons with autism span education and psychiatry, programs often developed in separate service systems, and persons with autism were served in other programs that often failed to recognize the full spectrum of their needs. For example, some adults with autism were served in statewide centers designed to serve adults with schizophrenia, and these programs did not always recognize and address the fundamental deficits in

social and other skills of adults with ASD. Other adults with autism were served in statewide centers designed to serve adults with intellectual disabilities and other psychiatric or conduct disorders, and these programs did not always recognize and address areas of special interest or relatively intact ability. Asperger syndrome was not yet recognized, and the persons affected often received little or no services.

Despite radical changes in the design and delivery of services at the local and the statewide level in the last two decades, the vestiges of this traditional split between educational, health, and psychiatric/behavioral health service systems are still evident in the structure and funding at the statewide level. While we have witnessed an explosion in the range of services designed more specifically for persons with ASD, these are rarely organized via a unitary, statewide structure specific to ASD. They are more often organized via loose partnerships between universities and other specialized centers, or via programs designed to meet the needs of a broader population (see below). These partnerships and programs tend to address a narrow band of the spectrum of needs, and rarely integrate services and supports across traditional service system boundaries.

Rationale or Underlying Theory

With some exceptions (described below), statewide service programs tend to be distinguished less by a specific theoretical orientation than by a structure that ensures reasonable access to services to all eligible clients across the state, or training to the providers who support them. If state agencies seek to influence local service delivery, it is usually through the training provided, or via the broad parameters embodied in licensing and certification requirements.

We describe below various approaches to statewide service delivery. While our description is by no means exhaustive, we believe that these examples characterize the range of approaches used. And while some of the specific programs cited are among the most prominent, no doubt, there

are other examples of innovative and effective programs that we have not described here.

The first, and perhaps best known, statewide service program is the TEACCH (Treatment and Education of Autistic and related Communication-handicapped CHildren) program based at the University of North Carolina (UNC) (Mesibov et al. 2005). While readers seeking more information about the specific theoretical approach are referred to the entry regarding TEACCH, some characteristics regarding their model of service delivery can be highlighted here. First, TEACCH is one of the first attempts to develop and strategically disseminate a specific educational model for persons with ASD across a state using a coordinated program of training. Every year, TEACCH faculty offer comprehensive training that follows a structured curriculum, at multiple sites and including summer sessions, to increase accessibility to educators. Second, TEACCH is also one of the first attempts to take full advantage of the state university infrastructure to increase accessibility to ASD-specific training and services: In addition to its headquarters at UNC-Chapel Hill, TEACCH sites can be found on other campuses of UNC. TEACCH remains one of the few university-based consortia to have offered specific services (e.g., consultation and assessment) in addition to training, and to provide training that spans traditional public school and adult service systems.

Since the establishment of TEACCH, a number of other university-based programs have sought to provide training or services on a statewide basis. The West Virginia Autism Training Center (WV-ATC) at Marshall University was established in 1983 by the state legislature, and has since undertaken a number of statewide programs through a combination of state and federal grants. For example, the Family Focus Positive Behavior Support program was established initially in 1996 through a grant from the Centers for Disease control, and has since expanded through support from the state legislature. The project provides education specialists to facilitate collaboration between family and school and other team members in the development and implementation of behavior support plans across

the state of West Virginia (Becker-Cottrill et al. 2003). The Indiana Autism Resource Center (IRCA), established in 1985 at Indiana University Bloomington, serves as a hub for a wide variety of training events and information about ASD. Both WV-ATC and IRCA also serve statewide needs' assessment functions as designated by their legislatures: WV-ATC established the first state autism registry, and IRCA has conducted triennial needs' assessment to inform state planning. A wider variety of university-based centers providing training across a region have been established or have increased their emphasis on ASD within the past 10 years, many of which are part of the network of University Centers of Excellence on Developmental Disabilities (see www.aucd.org).

There are other examples of statewide service and training programs that are not university based, but that grow out of agencies for public education or welfare. The Delaware Autism Program (DAP) is a consortium of public school programs that together serve the majority of students with ASD in the state (please see the entry for DAP for more information). The Commonwealth of Pennsylvania has implemented a variety of ASD-specific training programs that are primarily organized and/or funded more directly by state agencies. For example, the Pennsylvania Training and Technical Assistance Network (PaTTAN), within the department of Education, has created a network of model classrooms using the verbal behavior and the competent learner models. PaTTAN also helps to convene the National Autism Conference, which includes specific tracks for family members and professionals. The Pennsylvania Bureau of Autism Services was established within the Department of Public Welfare in 2003 to fund and coordinate a wide variety of statewide training and service programs. Many of these specifically complement education-based services by focusing on adults with ASD, or community-based early identification and behavioral support. In general, the most common statewide training programs impacting ASD would be those addressing the implementation of positive behavior supports; though not specific to ASD, these have great potential because challenging behaviors are perhaps the most likely reason for persons with ASD to be excluded from

public schools and other community-based settings.

More recently, a number of federal grant-funded programs have sought to disseminate training in a coordinated way at a statewide level. The National Professional Development Center for Autism (NPDC), funded by the Office of Special Education Programs, U.S. Department of Education, currently involves the collaboration of the University of North Carolina at Chapel Hill (Frank Porter Graham Child Development Institute), the University of Wisconsin (Waisman Center), and the University of California at Davis (M.I.N.D. Institute). The NPDC supports the development of ASD programs within the public schools by helping states to create statewide teams. These teams create model classrooms and develop training programs within their state. The Act Early Campaign orchestrated by the Centers for Disease Control (Daniel et al. 2009) has sought to create cross-agency statewide teams to identify opportunities to improve early detection and intervention in ASD.

Goals and Objectives

In addition to the goals and objectives set by individual clients and their caregivers, the goals most distinct to statewide service programs are those intended to make designated services directly accessible to the full range of eligible clients. In some cases (e.g., early education and intervention services), specific regulations mandate the rapidity with which such services are provided. Consistent with research documenting disparities in early identification and various aspects of intervention (Liptak et al. 2008), we would expect that some statewide service systems may face significant challenges when trying to ensure equal access for individuals and families from racial and ethnic minorities, at or near poverty level, and from rural regions.

Treatment Participants

Eligibility requirements vary from program to program, and usually reflect the general criteria

for accessing the service (e.g., only individuals between 3 and 21 years of age are eligible for services provided or funded via public schools). Because publicly funded statewide service programs are otherwise often designed, if not explicitly mandated, to be freely accessible, eligibility criteria are kept to a minimum. Some of the training programs (e.g., PBS) are intended to support a broad range of children and adolescents.

Treatment Procedures

Recommended treatment procedures reflect the specific focus of the training or service program.

Efficacy Information

While there may be data regarding the efficacy of specific treatment procedures employed or recommended by statewide service programs, there are at present no data that clearly demonstrate the specific efficacy of statewide service programs in providing or facilitating the use of these treatment procedures across a sample of clients that is representative of the population of the state.

Outcome Measurement

While outcome measures for specific treatment procedures employed or recommended by statewide service programs may be described elsewhere, there are at present no models for defining the acceptable outcomes for statewide service programs per se. Statewide service programs seeking to evaluate outcomes related to access could estimate the proportion of eligible individuals who receive services, or who experience significant barriers in accessing services.

Qualifications of Treatment Providers

ASD-specific qualifications for service providers are rarely defined for a specific statewide service or training program. Regulations established by

the state for specific categories of providers (e.g., special education teacher certification, psychologist licensure, etc.) usually represent minimal criteria, and rarely reference ASD-specific competencies. Exceptions include ASD teacher certification requirements or endorsement opportunities implemented in several states with statewide service programs (e.g., teachers in the Delaware Autism Program must complete a graduate-level teaching certificate in ASD to continue teaching students with ASD). The increasing recognition of behavior analysts by state licensure boards, the growing consensus that Board Certification is a minimal entry criteria, and the central role played by behavior analysts in treatment, all suggest that ASD-specific competencies are likely to be first established by states for behavior analysts.

Statistical Approaches to Subtyping

Daniel Campbell
Yale Child Study Center, Yale University, New Haven, CT, USA

Definition

Subtyping or *clustering* is a type of data analysis that seeks to assign elements of a set into groups, or clusters, that are similar (in some sense) to each other, but different from elements in other clusters. It is distinct from *classification*, in which one or more group labels already exist and the algorithm attempts to explain these labels using observed variables; instead, clustering procedures attempt to create such labels from the observed variables directly. For this reason, classification methods are sometimes called “supervised” methods because there are group labels available to “supervise” the partitioning of the data, while clustering methods are termed “unsupervised” because no such labels exist.

Historical Background

As long as there has been data, there has been a desire to find subtypes within data. The historical roots of this emphasis can be seen in taxonomy, where the interest in clustering species into different phylogenetic categories extends back to ancient Greece. However, the statistical approach to subtyping is a relatively recent phenomenon, made possible primarily by the modern computer, which made numerical analysis of large datasets possible. Since then, there has been increasing interest in searching for and understanding subtypes in a wide variety of scientific disciplines, including psychology, where the subtyping of individuals based on their measurements on psychological markers and the categorizing of different types of psychiatric disorders have been frequent topics of research.

Current Knowledge

Three of the most popular and useful approaches to clustering are *k*-means, mixture modeling, and hierarchical clustering. They are all readily available in common statistical software packages such as SPSS, SAS, and R.

K-Means

K-means is a popular clustering algorithm that assigns observations to clusters based on how close they are to cluster centers. The algorithm takes the data in matrix form, with the n observations as rows and the p variables/measurements as columns, and computes distances from each observation to each of k cluster centers using Euclidean distance, the classic distance formula taught in school. *K*-means then assigns each observation to its closest center, recalculates the k cluster means (hence the name), and repeats this back-and-forth process until the cluster assignments do not change anymore and the algorithm has “converged.” An example of a set of clusters obtained via *k*-means with two variables, 100 data points, and $k = 3$ clusters is shown in Fig. 1.

The *k*-means algorithm is computationally very fast, and the clusters it provides tend to be roughly comparable in size and shape. It requires specification of the number of clusters (see section “[Determining the Number of Clusters](#),” below), and making the wrong choice can yield poor clustering results. Also, because it uses Euclidean distance, it works best when all measurements are on the same scale, or else the variable with the largest range will dominate the distances between points; the data can always be scaled to adjust for this, however. Another limitation is that *k*-means is not designed to handle categorical measurements (because the distance between categorical labels, e.g., “Yes,” “No,” and “Maybe,” is undefined).

Mixture Modeling

A broad set of clustering methods are collectively known as *mixture models*. In these methods, a number of “latent” or unknown subgroups are assumed, and a probability distribution for each subgroup is specified. For example, the

Statistical Approaches to Subtyping,

Fig. 1 *K*-means results using $k = 3$ on a sample two-dimensional dataset with 100 observations, with the clusters differentiated by color. The X's indicate the centers of each cluster

observations from each cluster may come from a multivariate Normal distribution, with an unknown mean and standard deviation. Then, for each observation, the model can calculate the probabilities of belonging to each cluster: 90% for Cluster 1, 5% for Cluster 2, etc. The final cluster assignment for each observation is chosen as the cluster with the largest probability.

Mixture models have a lot of advantages. First, unlike in *k*-means where clusters tend to be compact and circular in shape, the latent clusters found in a mixture model can take any arbitrary shape, which provides a lot of freedom for the researcher. Second, the cluster assignments in *k*-means and other methods are absolute – an observation either belongs to a given cluster or it does not, and each observation can only belong to one cluster at a time. In mixture modeling, on the other hand, there is a measure of uncertainty in the cluster assignments, so if an observation is on the border between two cluster regions, it can have a 50–50 chance of belonging to either one. This can be very helpful in understanding how well the cluster assignments describe the data, and in identifying outliers that do not fit easily into any of the clusters.

Like other clustering algorithms, mixture models require you to specify the number of clusters, k . In addition, they also require that the distributions of each cluster be specified as well, which can yield a poor fit to the data if they are chosen incorrectly. While this can make the use of mixture models somewhat more complicated, the added complexity also allows clustering of more interesting and complex types of data, such as longitudinal data. By placing certain assumptions on the correlations between variables, mixture modeling can find clusters in sets of curves; popular variants of mixture modeling that do this are latent cluster analysis and latent trajectory analysis, and they have extensive applications to the longitudinal analysis of autism spectrum disorders.

Hierarchical Clustering

Methods like *k*-means build their clusters by calculating the distance of each cluster to some cluster center. The cluster centers are not observations themselves, they are just arbitrary points. Alternatively, one could build clusters by grouping together observations that are close to each

other, and far apart from the others. This is the strategy employed by hierarchical clustering.

The hierarchical clustering algorithm takes the set of all pairwise distances – distances from every observation to every other observation – and merges observations together into sets if they are very close to each other. The two closest observations get merged first, followed by the next two, and so on. The algorithm also needs one other piece of information: instructions on how to define the distance from a set to other observations (or other sets), given the pairwise distances. This piece is called the *linkage criterion*, and there are many to choose from. Using *single linkage*, the distance from an observation to a set is the minimum distance to any of the members of the set – two sets are close if they have a “single link” making them close together. *Complete linkage* instead uses the maximum distance to any member of the set, and two sets will be close under this criterion only if every pair of observations is close to each other. *Average linkage* attempts a compromise between single and complete linkage, and averages the minimum and the maximum distances. Ward’s method takes a different approach, and combines the observations/sets together that give the smallest increase in variability by merging, so that each new cluster has the smallest possible variance.

Hierarchical clustering continues combining sets until all observations have been merged into a single, all-encompassing cluster. The end result is a *cluster tree* or *cluster dendrogram* made up of nested sets of clusters, where a pair of clusters is merged to give the cluster solution with one fewer label. As such, it provides the cluster solution for all values of k simultaneously, although it is still up to the researcher to determine which value of k to choose. Examples of cluster trees using four different linkage criteria are shown in Fig. 2.

Determining the Number of Clusters

Determining the “correct” number of clusters is one of the most difficult aspects of clustering. Because there is no known “true” grouping in the data (if there were, clustering analysis would not be necessary), there is no way to know how correct any clustering result actually is, and

instead alternative means of assessing the validity of a clustering result must be used. Such methods can be internal, by looking at the statistical differences between clusters on the same variables used to make the clusters, or external, by relying on other variables not included in the clustering analysis to validate the clusters.

Choosing the number of subgroups using internal aspects of the cluster solution is commonly done by means of a *scree plot*. A scree plot graphs the number of clusters, k , on the x-axis, and a measure of variability or dispersion of the data on the y-axis. Typically the y-axis is the *sum of squares*, which is an unscaled version of the sample variance. An example of a scree plot is given in Fig. 3. When $k = 1$, the sum of squares gives the default amount of variability in the data; for larger values of k , the sum of squares will be smaller because the clusters explain some of this variability. The scree plot shows how much explanatory power (measured by a drop in variability) is gained by each additional cluster, with big drops in variability for the first few clusters, but much smaller drops as more and more clusters are added because much of the variability is already captured by earlier clusters. A scree plot can suggest the best choice of k if it displays a “kink” or “elbow,” where the marginal benefit of adding more clusters is relatively small and a more parsimonious clustering is preferable.

External information can also be very useful in choosing the preferred number of clusters. A set of clusters can be validated though hypothesis testing, e.g., comparing differences in means between clusters using Student’s t -test (for two clusters) or an analysis of variance (for three or more clusters). Statistically significant differences between some or all of the clusters on variables not used in the clustering algorithm can indicate meaningful differences between the subgroups. If some clusters do not exhibit statistically significant differences from each other, then they can perhaps be merged together. Care should be taken not to read too much into differences among the variables used to create the clusters, however, because the clustering procedure is designed to maximize differences on these variables, so they cannot serve as outside sources of validation.

Statistical Approaches to Subtyping, Fig. 2 The results of hierarchical clustering using four different linkage criteria on the same dataset used in Fig. 1. Notice that single linkage tends to produce many tiny clusters, while average linkage and Ward's method favor larger groups.

While the overall tree structures are markedly different, on this particular dataset complete linkage, average linkage, and Ward's method give nearly the same subgroupings if the tree is cut into three clusters. This is because the data strongly displays a three-cluster structure, as seen in Fig. 1

Ultimately, the determination of the number of clusters is an art, not a science, and the strategies described here should be treated as rules of thumb. While scree plots and hypothesis tests can give some insight into the right number of clusters, equally important are the principles of parsimony and interpretability. If two clusters appear different on a few variables but not others and are small in size, then they can (and perhaps should) be merged to give fewer subgroups that are easier to understand. Choosing between five and six

subgroups, for instance, is far less important than understanding what these subgroups represent to the researcher and to his or her scientific field.

Future Directions

The subtyping methods described here work well for datasets in which the number of variables, p , is relatively small compared to the number of observations, n . When the number of variables is much

Statistical Approaches to Subtyping, Fig. 3

A scree plot showing the decreasing sum of squares with increasing k , using k -means on the same data as in Fig. 1. Notice the “kink” at $k = 3$, suggesting three subgroups in the data

larger than the number of observations, the data is said to be *high-dimensional*, and these methods may become computationally slow, or fail to give satisfactory results at all. Such datasets are increasingly more common in genetics and eye-tracking studies, so statistical research is currently ongoing to develop subtyping methods that work well in the high-dimensional setting. A few of these newer methods are subspace clustering, projected clustering, and correlation clustering.

Statistical Significance

Domenic V. Cicchetti
Departments of Psychiatry and Biometry, Yale
Child Study Center, Yale University, New Haven,
CT, USA

Definition

Statistical vs. Clinical Significance: Statistical significance means simply that a result in a given comparison occurs beyond what one would expect by chance alone. Here, and by accepted convention, a comparative result is declared statistically significant if it occurs at or beyond the 5% level. By simple subtraction, this means that there is a 95% possibility that the result did not occur by chance.

The caveat here, and one that many journal editors and even some unenlightened biostatisticians fail to grasp, is that given a large enough number of cases or N, a given comparative result will inevitably occur *beyond chance*, at the 5% level of statistical significance.

In order to guard against this so-called big N phenomenon, enlightened biostatisticians have devised guidelines for defining a result as having reached a level of clinical, as well as statistical significance.

A concrete example, albeit an apocryphal one, can be derived easily from the field of autism spectrum research.

Suppose an inexperienced clinician on a scale of 0–100% agrees with the diagnosis of childhood autism, in 500 cases at 10%. With such a large N of cases, the result turns out to be statistically

significant with a chance probability at the scientifically acceptable level of 5%.

Well, any self-respecting autism expert would tell you that 10% chance-corrected agreement, from a clinical perspective, is poor or trivial.

Clinical significance to the rescue comes in the form of a set of clinical criteria developed by Cicchetti and Sparrow (1981) by which:

- Agreement Clinical
- Level of significance:
 - <40%, Poor
 - 40–59%, Fair
 - 60–74%, Good
 - 75–100%, Excellent

Stay-Put Requirement

Kevin Barry
Quinnipiac University School of Law, Hamden,
CT, USA

Synonyms

- [Placement-pending requirement](#)

Definition

In General

“Stay-put requirement” refers to a provision in the Individuals with Disabilities Education Act

(IDEA) (20 U.S.C. § 1415(j) (2011)) that gives a child the right to “stay put” in his or her current educational placement pending resolution of a dispute between the child’s parents and the school district. Under the IDEA, school districts must provide special education and related services to “children with disabilities,” which specifically includes children with autism. When parents and the school district cannot agree on the special education and related services provided to a child, parents and the school district have the right to file a “due process” complaint requesting a hearing before an impartial hearing officer. Once a due process complaint is filed, the child must “stay put” unless the parents and school district agree otherwise (or unless the school district places the child in an “interim alternative educational placement”). For example, if a school district notifies the parents of a child with autism that their child is no longer eligible for special education and related services, the parents have the right to file a due process complaint. Under the IDEA’s stay-put requirement, the child will continue to receive special education and related services pending resolution of the dispute. Similarly, if a school district notifies the parents of a child with autism that the district wants to remove the child from a private special education placement and place the child back in the public schools, and if the parents disagree, the parents have the right to file a due process complaint and invoke “stay put” pending resolution of the dispute.

In the Disciplinary Context

The stay-put requirement has special importance in the disciplinary context. If a child with a disability violates a code of student conduct, school districts are free to suspend the child for up to 10 consecutive days. The rules governing discipline of children with disabilities for more than 10 consecutive days are complex. Generally speaking, if a school district determines that the child’s misconduct was not a “manifestation” of his or her disability, the district may expel a child with a disability or suspend the child for more than 10 consecutive days so long as it provides educational services in an alternative setting. (If the misconduct involves

weapons, drugs, or serious bodily injury, the school district may suspend the child for up to 45 days even if his or her behavior was a manifestation of his or her disability.) Importantly, in the disciplinary context, the filing of a due process complaint does not require that the child “stay put” in his or her “predisciplinary” placement. Rather, the child will remain in his or her alternative educational placement pending resolution of the dispute.

► Trifluoperazine

STEM Education and Autism Spectrum Disorder

Stephen Hegedus and Marie Nabbout-Cheiban
School of Education, Southern Connecticut State
University, New Haven, CT, USA

Definition

Our fundamental definition of how the fields of educational research and Autism at large interact is through the development of multimodal interactive learning environments as teaching and learning tools to improve the mathematical knowledge and problem-solving skills for learners with Autism Spectrum Disorders (ASD). Such interventions establish a potential importance for their use in special needs education in general. In particular, STEM learning environments offer natural multimodal interactions to enhance the accessibility to complex mathematical and scientific ideas through technological affordances. Multimodal interfaces exist as combined input/output methods or as an alternative input, such as speech inputs (e.g., voice recognition), bodily motion, and touch (e.g., gesture-based interactions). The latter has evolved in recent years with the development of multitouch technologies (e.g., tablet PCs, Interactive Whiteboards, iPads). Combined input/output devices include haptic devices, which integrate visual modes with force feedback loops, offering the user the ability to feel objects or the results of

Historical Background

Learners with Autism Spectrum Disorders represent one of the underrepresented STEM talent pools in the United States (Wei et al. 2012, 2013), since they have an innate attraction to STEM fields (Baron-Cohen et al. 2007; Baron-Cohen 2009) and they are more likely than the general population and other disability groups to choose a STEM major (Wei et al. 2012). Despite their potential to succeed in STEM fields, interest and ability alone may not be sufficient enough to enable a learner with Autism Spectrum Disorders to pursue a STEM major in college (Wei et al. 2015). The data from the National Longitudinal Transition Study-2 (a nationally representative sample of students eligible for special education with an autism spectrum disorder) show that 34.1% of learners with ASD declared a major in STEM field in postsecondary education compared to 22.80% of students in the general population (Chen and Weko 2009). The issue with learners with ASD, however, is postsecondary enrollment, where the rate of learners with ASD is the third lowest of all the disability categories: 30% versus 66% of general population (Wei et al. 2012). The main barriers that learners with ASD face in their learning are related to their challenges in executive functioning and social communication: social interaction, flexible thinking, perspective taking, awareness of and adherence to social rules, language flexibility and discourse skills, motivation, and engagement (Hendricks and Wehman 2009). Research has indicated that learners with ASD use ineffective strategies for problem-solving because they may often focus on irrelevant information, and may not consider outcomes prior to the use of a strategy (Bauminger 2007; Solomon et al. 2004). The problem-solving skills that were studied are not mathematical, but rather related to daily routines, and there is a lack

of research on how students with high-functioning autism can demonstrate executive functions in mathematical problem-solving.

In a review of the literature of Computer-Assisted Instruction (where a computer is used to learn the material and for assessment) between the years of 1997 and 2008, Pennington (2010) inferred that Computer-Assisted Instruction may have promise as an effective intervention for ASD learners, as most of the studies showed effectiveness for teaching academic literacy skills. In 2011, Wainer and Ingersoll concluded that the use of innovative computer technology is a promising strategy for delivering direct intervention to children and adults with ASD. What is missing, according to the authors, is demonstrating the efficacy, effectiveness, and social validity of such interventions across diverse samples of individuals with ASD.

Current Knowledge

The use of computerized environments permits the development of skills in a predictable and controlled environment, while allowing students to work at their own pace and ability level (Golan and Baron-Cohen 2006). These features may be particularly beneficial for learners with Autism Spectrum Disorders given that they often experience discomfort in unpredictable social environments (Charlop-Christy et al. 2000). Learners with ASD typically have strong visual processing skills and a predisposition towards electronic media. Accordingly, interventions using computer technology would be particularly appropriate and motivating (Shane and Albert 2008). The use of interesting visual and auditory stimuli to engage users may be beneficial for learners with ASD given their relative strength in visual processing (Rayner et al. 2009). More importantly, learners with ASD have an innate tendency to gravitate toward STEM fields (Baron-Cohen 2009; Baron-Cohen et al. 2007). They have relatively greater aptitude to analyze or construct rule-based systems to explain the world around them, than to social and emotional reactions to other people's thoughts and feelings (Baron-Cohen 2009).

Systemizing often requires the thinking or skills needed to analyze and construct systems, which also are necessary to perform successfully in many STEM-related fields (Baron-Cohen et al. 2007).

In Mathematics Education research, the use of dynamic interactive representationally rich environments has dominated the design and curriculum space for 25 years with basic and applied research in studies focused on learning, teaching effectiveness, motivation, and collaborative learning (Hegedus and Roschelle 2013). Science Education has utilized similar design spaces but have primarily focused on Logo, and virtual and augmented reality environments focused on real-world issues including climate change and urban planning to name a few. As we build out into a space of learning for all, we notice a lack of attention (or extension) to learners with exceptionalities or specifically, learners with ASD. Multimodal interaction has evolved in various research areas and applications including computer vision/visualization, psychology, and artificial intelligence with increasing use in education particularly in early learning and developmental psychology. Jaimes and Sebe (2007) offer a survey of many of these disciplines including face recognition, facial expression analysis, vocal emotion, gesture recognition, human motion analysis, speech recognition, and eye tracking. They outline how a multimodal interaction can simply be an environment that responds to inputs in more than one modality or communication channel (e.g., speech, gesture, writing) through perceptual, attentive, or enactive interfaces. Dautenhahn (2003) has developed multimodal interactive learning environments as teaching and learning tools for the rehabilitation of children with autism, which establishes a potential importance for their use in special needs education in general.

Future Directions

It is our current goal to understand the interaction of learners with Autism Spectrum Disorders utilizing the current affordances of educational

technology, and to understand their interactivity in a multimodal environment. Learners with ASD have innate attraction to STEM fields and engage well with technology, but are underrepresented in STEM fields and as previous research has shown, inflexibility in thinking hinders their performance. Future work needs to focus on designing and implementing learning environments that focus on improving the executive functions and mathematical problem-solving skill development for learners with ASD. These environments will serve as accommodations for the needs of learners with Autism Spectrum Disorders to learn high-quality mathematics, rather than simplifying the content. Multimodal technologies provide an effective medium through which customizable supports may be provided to learners with ASD that have a variety of needs.

The fields of STEM (particularly Mathematics Education) research needs to fully understand the democratizing effect of examining each and every learner within its design paradigm. Much of the design, efficacy, and large-scale implementation studies through randomized controlled trials over the past two decades can be tested with learners with ASD. More specifically though, we need to focus on what kinds of experimental and methodological supports are necessary to conduct such work. Are traditional research methods necessary and sufficient for such work particularly when we are examining communication skills? Traditional educational research methods focused on discourse and think-aloud protocols, or semi-structured interviewing protocols, might well not be sufficient. Do we focus on less qualitative and more behavioral techniques? Ultimately, our responses are subject to what is needed in schools today: to shift the mindsets of teachers and support staff but ultimately to carefully examine, unpack, and rebuild the art of teaching and learning for each and every learner.

other, non-ASD, disabilities (Roux et al. 2013). Generally, quality of life is also relatively poor (van Heijst and Geurts 2015) and social inclusion is limited (Howlin et al. 2013).

The Stepped Transition in Education Program for Students with ASD (STEPS) is an individualized therapeutic program to support transition into postsecondary education for adolescents and young adults with ASD. STEPS was designed to be developmentally appropriate, such that students facing high school graduation receive support related to preparing for the transition (Step 1), while those in college receive support related to social inclusion and academic success in post-secondary education (Step 2).

Stepped Transition in Education Program for Students with ASD (STEPS)

Susan W. White

Alabama, Tuscaloosa, AL, USA
Psychology Department, Virginia Tech,
Blacksburg, VA, USA

Definition

Students with ASD have unique transition needs that go largely unmet. The transition from adolescence to adulthood (spanning approximately age 18–25) represents a distinct developmental period termed “emerging adulthood” (Arnett 2010). It is during this developmental period that people with ASD who do not have co-occurring intellectual disability appear to be most vulnerable, as they often face loss of services and supports to help them achieve important developmental tasks such as beginning higher education and establishing close and intimate relationships (Taylor and Seltzer 2011). In fact, many students with ASD report feeling ill-prepared for success in the postsecondary domain (Cai and Richdale 2016). Most adults with ASD are employed neither consistently nor gainfully (Engström et al. 2003) and, when employed, they tend to be paid less than young adults with

Historical Background

With heightened awareness of ASD, earlier diagnosis, development of more effective interventions, and greater recognition of ASD among people who do not have co-occurring intellectual disability, the population of cognitively able adolescents and young adults with ASD interested in higher education and career attainment has been steadily rising (White et al. 2011). For a host of reasons, however, young people with ASD often do not enroll in college or, once matriculated, exit prior to graduation. Low levels of educational attainment are associated with later disadvantage in the work place. Although academic supports are often in place to support college students with learning disabilities (Cai and Richdale 2016), support personnel in the university setting often are unprepared to support the host of nonacademic needs with which some students with ASD present (VanBergeijk et al. 2008).

Research has shown that difficulties with self-regulation, social isolation, and task management are among the primary challenges of college students with ASD, and these difficulties may contribute to unsuccessful outcomes (e.g., White et al. 2016a). Additionally, there is evidence that the needs of college students with ASD are fairly unique and distinct from those seen among college students with disabilities such as attention-deficit/hyperactivity disorder (Elias and White

2017). Intervention and support to address these difficulties may contribute to greater odds of success in postsecondary education for students with ASD.

Rationale or Underlying Theory

STEPS is based on cognitive-behavioral theory of change and, as such, the content addresses the student's thoughts, feelings, and behaviors in the here and now. Content of each session is fairly modular and skill-focused. Between-session assignments are used to practice skills and reinforce learning, and every session follows a goal-based agenda.

Mechanistically, STEPS targets two related processes – self-regulation and self-determination. Change in these mechanisms is theoretically believed to mediate observed increases in readiness for transition to college (Step 1) and improvement in college adjustment (Step 2). Self-regulation is a multifaceted construct involving monitoring and modulation of behavior, emotion, and thought (Baumeister et al. 2007). Self-determination includes the ability to identify, set, and then achieve goals.

Among students with disabilities, self-determination has been found to predict adult outcomes (e.g., Chambers et al. 2007). Skills related to advocating for one's needs and appropriate disclosure of the ASD diagnosis are addressed in relation to self-determination. Students in STEPS learn strategies to improve self-regulation as well; cognitive flexibility, stress management approaches, and problem-solving are covered. Self-regulation is related to the difficulties commonly seen in young people with ASD in managing intense emotion (e.g., Mazefsky et al. 2013).

In light of research suggesting limited generalizability of observed treatment effects in ASD samples, and the benefit of parental support to intervention success, STEPS utilizes the input and support of stakeholders in the student's life (e.g., parents) as well as frequent in situ training. In Step 1, students participate in a college immersion experience, and in Step 2, students participate in several social outings with their therapist,

during which they practice skills (e.g., stress management, social initiation). Additionally, there is online content covering the primary STEPS modules, made available to the students, their parents, and identified school personnel, so that skills can be reinforced by other people in the student's life.

Goals and Objectives

STEPS has two primary goals: to promote successful transition into postsecondary education and to improve the college experience. As such, there are two levels within STEPS – Step 1 is for secondary school students planning for graduation and college matriculation and Step 2 is for students enrolled in community college or 4-year university.

Treatment Participants

Step 1 was developed for students with a diagnosis of ASD who are either in secondary school (high school) or who have graduated but are not yet enrolled in college. Students must be 16 years old (so that they are likely in their last 2 years of high school) and have no intellectual disability, given that the goal of the program is to help prepare the student for higher education as well as the verbal demands of the program. The student need not know their postgraduation plans, but STEPS is most appropriate for students who plan to attend either community college or university after high school. Step 2 is for young people with ASD who are college-enrolled. The program is appropriate for students regardless of type of college (e.g., community college, university) or field of training (academic major).

Treatment Procedures

Step 1 is comprised of six counseling sessions, plus a day-long college immersion experience, held over a course of approximately 12–14 weeks. Each student has an identified “school personnel” (oftentimes a teacher who knows the student well)

who participates in the program as well. This identified school personnel receives in-person training, which takes place over the course of two school in-services, during which research-supported strategies for supporting students with ASD during transition from secondary school are presented and discussed. These in-services provide opportunities for role-play, skills practice (among the school personnel), and sharing of ideas among the group of school personnel as well.

Step 2 is comprised of 12–13 individual sessions (student and therapist). These sessions, along with the community-based outings, are held over a 12–16-week period. Each student in Step 2 receives 4–6 community-based outings, the goal of which is to practice new skills related to self-determination and self-regulation in social settings and increase the student's social involvement. As such, outings might involve activities such as joining a new social club on campus or applying a part-time job.

Although students, parents, and school personnel (once identified) are invited to use the STEPS online content, the parents and school personnel are much more actively involved in the program in Step 1 than in Step 2. In Step 2, the student acts more autonomously, and often the parents are not living nearby.

STEPS is individualized to the needs of the particular student. As such, the timing of the sessions, as well as the content and context of the social outings in Step 2, and the goals of the immersion experience of Step 1, are designed to address the needs of the student. Within this flexibility, there are core content sessions for each Step.

Efficacy Information

There is no efficacy data on STEPS at the time of this publication, although a randomized controlled trial (RCT) of the intervention is nearing completion, with a sample of 50 adolescents and adults (aged 16–25) who have ASD. In the preliminary study on feasibility, college students with ASD reported considerable satisfaction with the intervention and there were no drops from intervention (White et al. 2016b). Based on incomplete

data from the current RCT, students and parents have reported that the program is quite helpful (mean = 4.38 and 4.39, respectively, for students and parents, on a 1- to 5-point Likert scale).

Outcome Measurement

STEPS was developed to improve postsecondary outcomes for students with ASD. As such, for Step 1, the primary outcome variable is readiness for college transition, measured with a scale developed for this project that assesses preparedness for transition across three domains: cognitive (expectations, awareness of needs), emotional (fears related to transition), and behavioral (skills needed for postsecondary success). For Step 2, the primary outcome variable is college adjustment, measured with the Student Adaptation to College Questionnaire (SACQ; Baker and Siryk 1999).

In addition, secondary outcomes related to emotion regulation, quality of life, and adaptive skills are assessed throughout the intervention and at 3-month follow-up after STEPS completion. Data are collected from student participants as well as parents and school personnel.

Qualifications of Treatment Providers

Therapists for STEPS should have prior experience working with adolescents and young adults with ASD. In the current RCT, supervision is provided by a licensed clinical psychologist (PhD level) and therapists have been doctoral students in clinical psychology and education.

Stereotyped Movement Disorder

Mark Lewis

College of Medicine, University of Florida,
Gainesville, FL, USA

Synonyms

Repetitive behavior; Self-injurious behavior; Self-stimulatory behavior; Stereotypy

Short Description or Definition

Stereotyped movement disorder (SMD) refers to motor behaviors characterized by repetition of the

same movements that are seemingly driven and which have no obvious purpose or function (APA 2000, DSM-IV TR). Prior to 1994, SMD was referred to by the American Psychiatric Association as stereotypy/habit disorder. Examples of SMD-related behaviors include hand flapping, body rocking, head rolling, twirling or spinning objects, as well as behaviors that can be self-injurious (e.g., self-hitting, head banging, self-biting). To meet diagnostic criteria for SMD, the behavior needs to interfere with normal activities or result in injury requiring medical treatment and last longer than 4 weeks. Additional criteria require that if mental retardation (currently intellectual and developmental disability) is present, the behavior must be of sufficient severity to become a focus of treatment. In addition, to warrant the diagnosis of SMD, the behavior is not better accounted for by a compulsion (obsessive-compulsive disorder), tic (tic disorder), or stereotypy that is part of a pervasive developmental disorder (PDD) or is not hair pulling (trichotillomania). Finally, the behavior should not be due to the effects of a substance (e.g., a psychostimulant like amphetamine or cocaine) or general medical condition.

In the proposed DSM-V, the relevant work group is recommending that SMD be classified as a neurodevelopmental disorder or an anxiety and obsessive-compulsive spectrum disorder. In addition, in the case of self-injurious responding, the behavior will likely no longer require medical treatment to meet diagnostic criteria. In addition, specification of 4 weeks or longer duration and the requirement that the stereotyped behavior be the focus of treatment will likely not be required for the diagnosis to be made. Instead, the behavior will need to result in clinically significant distress or impairment in important (e.g., social, occupational) areas of functioning (Stein et al. 2010). As in DSM-IV, the stereotypy cannot be consequent to the use of a particular drug or substance or restricted to the symptoms of another disorder (e.g., autism spectrum disorder or ASD, trichotillomania).

The hierarchical exclusion criteria operative in DSM-IV precludes the diagnosis of SMD if stereotypy is part of a pervasive developmental

disorder. With regard to ASD, however, SMD maps on to what has been characterized as the “lower order” or repetitive sensory-motor behavior factor of restricted, repetitive behavior (e.g., Szatmari et al. 2006). Repetitive sensory-motor behaviors are more characteristic of younger or lower functioning individuals with ASD.

Categorization

The SMD diagnosis is most frequently associated with intellectual and developmental disability (IDD), with the occurrence of stereotyped and self-injurious behavior being inversely correlated with degree of intellectual disability (Bodfish and Lewis 2002). Despite this, there has been little or no attempt to ascertain SMD in this population based on the diagnostic criteria reviewed in the previous section, particularly the criterion specifying that stereotyped behavior be the focus of treatment. In individuals with intellectual disability, SMD involving SIB is frequently accompanied by forms of self-restraint (e.g., binding hand or arms in clothing) designed to avoid self-injury, although self-restraint is only temporarily effective (Powell et al. 1996). The available evidence suggests little difference in form or pattern between repetitive motor behaviors in ASD and IDD, although the frequency appears to be higher in the ASD group (Bodfish et al. 2000).

There is growing evidence of the applicability of the SMD diagnosis in non-developmentally delayed individuals (Singer 2009). These stereotypes have been referred to as “primary” stereotypes or “physiological” stereotypes to distinguish them from those associated with a specific clinical disorder. It should be noted, however, that SMD appears to be comorbid with hyperactive behavior or attention-deficit problems as well as anxiety or affective problems. Although there has been little systematic attempt to differentiate stereotyped motor behavior in non-developmentally disabled individuals versus those with autism and related neurodevelopmental disorders, there seems to be considerable overlap in topographies or forms.

Stereotyped motor behavior has also been documented as a common consequence of psychosocial deprivation such as being reared in institutional environments (Bos et al. 2010), severe sensory deficits such as blindness, traumatic brain injury, and dementia, particularly the frontotemporal variety. In addition, stereotyped motor behaviors are commonly observed among typically developing young children. These developmentally appropriate behaviors include thumb-sucking, body rocking, hand flapping, and even transient head banging. These behaviors are self-limited and rarely result in tissue damage. The factors contributing to the progression of normative stereotyped behavior in infants and toddlers to persistent, developmentally inappropriate stereotyped motor behavior are unknown. The frequent expression of topographically similar forms of stereotyped behaviors in typically developing children presents an important challenge to identifying potential SMD in non-developmentally delayed children.

Epidemiology

Prevalence estimates for individuals who meet DSM diagnostic criteria for SMD are not available. There have been attempts, however, to estimate the rates of stereotypy and SIB in samples of individuals with IDD and in non-IDD individuals with “primary” or “physiological” stereotypies. In the former case, stereotypies have been observed in up to 80% of individuals with severe or profound intellectual disability residing in a state residential facility (Bodfish et al. 2000) whereas much lower rates (10–20%) have been observed in individuals who live in the community and have milder intellectual impairment. Self-injury is less common, being observed in 20–25% of individuals who are institutionalized and have severe or profound mental retardation (Bodfish et al.) whereas overall SIB rates vary from 4% to 10% (Arron et al. 2011). Interestingly, SIB rates ranging from 45% to 93% have been reported for individuals with specific genetic syndromes including fragile X, Angelman, cri du chat,

Cornelia de Lange, Prader-Willi, Lowe, and Smith-Magenis (Arron et al.).

The prevalence of complex motor stereotypies in a non-developmentally disabled population has not been established. In a retrospective study of referrals to pediatric neurology-movement disorders clinic, 100 children were identified with persistent “primary” or “physiological” stereotypies. Of these children, 62% were boys, age of onset was 24 months or younger in 80% of cases, and about half displayed comorbid conditions (ADHD, tics, OCD). Castellanos, Ritchie, Marsh, & Rapoport (1996) identified 12 non-IDD adults who met DSM-IV criteria for SMD. Body rocking or thumb-sucking was present in 8 of these 12, and a lifetime history of an affective or anxiety disorder was found for 11 of 12 SMD individuals. A family history of stereotypies, anxiety or mood disorders, tics, and ADHD has also been documented in non-IDD individuals exhibiting complex motor stereotypies (Harris et al. 2008).

Natural History, Prognostic Factors, and Outcomes

Little is known about the developmental timing of the transition from normative to pathological stereotyped behavior. In addition, little is known about environmental, behavioral, or genetic factors that influence or predict the developmental progression of stereotyped behaviors. It does appear, however, that when stereotypies persist beyond what is expected in typical development, they are usually chronic, although not worsening over time. In individuals with ASD, there is some evidence that repetitive sensory-motor behaviors decrease across development (Esbensen et al. 2009; Richler et al. 2010).

Unlike tics or OCD, stereotypies do not appear to have a natural history of waxing and waning. Stereotypies can be interrupted, however, and may vary in frequency depending on the emotional state of the individual. The factor most predictive of a diagnosis of SMD is IDD, with severity of SMD varying with intellectual impairment. Boys are more likely than girls to develop

the disorder with other predictive factors being early psychosocial deprivation, profound sensory impairment, a family history of stereotypies, tics, compulsions, or ADHD, and a comorbid disorder that includes tics, OCD, or ADHD. There is no evidence for birth history being a predictive factor.

Clinical Expression and Pathophysiology

Repetition of invariant sequences of behavior that appear to serve no obvious purpose has long been considered an important dimension of psychopathology. Abnormal repetitive behavior is part of the clinical presentation of a variety of disorders including ASD, OCD, Tourette syndrome, IDD, frontotemporal dementia, schizophrenia, Parkinson's disease, and substance abuse. Such behaviors have been labeled as stereotypies, compulsions, rituals, obsessions, punding, complex tics, self-stimulatory behavior, habits, and perseveration. SMD is more circumscribed, however, and refers to discrete motor responses such as body rocking, head rolling, finger flicking, hand flapping, and repeating the same words or phrases. In some cases, the stereotypy will involve repetitive object manipulation such as spinning or twirling a toy or household object. Other topographies are associated with self-inflicted tissue damage including head banging, biting, head or face slapping, and eye poking. In individuals with IDD, stereotypies can occupy a great deal of the individual's time and interfere with ongoing habilitative efforts and activities. SIB can be quite severe with potential loss of digits or lips from self-biting (e.g., Lesch-Nyhan syndrome) to delivery of self-inflicted blows to the head that have the force of a boxer's jab (Newell et al. 2002).

Beyond its general association with IDD, specific forms of SMD have been associated with specific genetic syndromes: skin picking in Prader-Willi syndrome; self-biting of the lips and fingers in Lesch-Nyhan syndrome; midline hand claspings in Rett syndrome; and hand flapping in fragile X syndrome to name but some (Lewis and Kim 2009). Understanding the pathophysiology

of these genetic syndromes will help inform the neural bases of SMD.

There is only one postmortem study that has linked SMD with a specific neuropathological finding (Lloyd et al. 1981). In this report of three Lesch-Nyhan cases, severe SIB was associated with markedly reduced striatal dopamine concentrations. Later, positron-emission tomography (PET) studies confirmed the loss of dopamine innervation to striatum in Lesch-Nyhan patients (Ernst et al. 1996; Wong et al. 1996). A number of clinical and animal model studies have provided additional support for the importance of alterations in basal ganglia dopamine function in stereotypy and SIB (Turner and Lewis 2002). Neuroimaging findings in ASD have linked repetitive behavior to altered caudate volume although this association involved "higher order" behaviors reflecting resistance to change or insistence on sameness not sensory-motor repetitive behaviors. Kates, Lanham, and Singer (2005), however, compared boys with stereotypies but no other known neurological or neurodevelopmental disorder with matched controls. Decreases in frontal white matter were observed in the stereotypy group even after controlling for total white matter. Caudate volumes did not differ between groups, however, after taking total brain volume into account.

Much of what we know about the pathophysiology of stereotyped motor behaviors comes from studies using various animal models (Lewis et al. 2007). These models can be categorized as induction of stereotyped behavior by (1) targeted CNS insults, (2) pharmacological agents, and (3) environmental restriction or deprivation. These models generally support a preeminent role for alterations (dopaminergic and non-dopaminergic) in cortical-basal ganglia circuitry in the expression of stereotyped behavior. This circuitry involves projections from select areas of cortex to striatum and then on to other basal ganglia (globus pallidus, substantia nigra), then to thalamus and finally back to cortex. At least three parallel but interacting loops have been identified that make up this cortical-basal ganglia circuitry: the motor, limbic, and associative loops. Of these, the motor loop appears to be the best candidate for

mediation of SMD. This loop involves both a direct and indirect pathway from striatum back to cortex. Dysregulation of cortico-striato-thalamocortical circuitry associated with motor disorders is thought to be due to an imbalance between the direct and indirect pathways comprising this circuit. Recent evidence from an animal model suggests that decreased activity of the indirect pathway is associated with higher levels of stereotyped behavior (Lewis and Kim 2009). A review of relevant animal models suggest that stereotyped and self-injurious behavior can result from a variety of perturbations (e.g., drugs, lesions, gene deletions) to this cortical-basal ganglia circuit.

Evaluation and Differential Diagnosis

As SMD should not better be accounted for by a compulsion, tic, or PDD-related stereotypy, careful assessment of the individual will be required to assess the presence of these other disorders. In addition, given the high prevalence of SMD in developmentally disabled individuals, careful assessment of IDD is also required. The diagnosis of SMD may be particularly challenging with regard to differentiation from complex motor tics. Stereotypies, however, typically have an earlier age of onset than tics; involve hands and arms versus face, head, and shoulders; and tend to be longer in duration and often rhythmic in expression. Careful attention should also be paid to assessment of conditions reported to be comorbid with stereotyped motor behavior (e.g., tics, ADHD, OCD). It will also be critical to differentiate developmentally appropriate and developmentally inappropriate stereotyped movements.

Although there is no “gold standard” diagnostic assessment tool for SMD, there are specific instruments designed to assess stereotyped and other repetitive behaviors. One of the more useful is the Repetitive Behavior Scale-Revised (RBS-R; Bodfish et al. 2000) which includes stereotypy and SIB subscales. The RBS-R is an informant-based rating scale with good psychometric properties that provides for both an endorsement of specific forms of stereotyped and self-injurious

behavior as well as ratings of intensity or severity of each item. Other options for assessment include the Childhood Routines Inventory (CRI; Evans et al. 1997), which includes items that load on a “just right” factor and a “repetitive activities” factor, and the Repetitive Behavior Questionnaire (RBQ; Arron et al. 2011), which has been used to examine stereotypy and self-injury in a number of genetic syndromes. Observational measures have also been used to provide more detailed assessments of frequency and duration.

Treatment

Both behavioral and pharmacological interventions have been used to treat stereotyped and self-injurious behavior. With regard to psychotropic medication, the two drug classes most commonly employed include atypical antipsychotics (e.g., risperidone) and selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine). A recent multisite study of the SSRI citalopram provided no evidence for its efficacy in treating repetitive behavior in autism (King et al. 2009). There is limited evidence for the utility of atypical antipsychotics in treating stereotyped and self-injurious behavior. Risperidone, the most widely studied drug in this class, appears to have some efficacy for SMD but may be better suited to the treatment of irritability and aggression. In addition, risperidone carries the risk of adverse effects including weight gain and metabolic syndrome. Aripiprazole appears to be useful in the treatment of stereotypies, but significant adverse effects have also been reported. Finally, the opiate antagonist naltrexone has been used in the treatment of self-injury, but reports are mixed as to its efficacy.

Behavioral treatments for SMD are generally based on operant learning principles and administered by behavior analysts (Rapp and Vollmer 2005). These interventions often follow completion of a functional analysis of the stereotyped or self-injurious behavior which is designed to identify existing socially mediated consequences that maintain the behavior. An example of such an assessment might show that whereas stereotypy is not affected by socially mediated

consequences, the self-injury of a particular individual results in either attention or escape from demands and is thereby reinforcing. Alternative appropriate behaviors designed to result in attention or escape can then be shaped and reinforced. This strategy is referred to as differential reinforcement of other (or alternative or incompatible) behaviors (DRO/DRA/DRI). This treatment can also be used in conjunction with response interruption. Another intervention strategy is functional communication training (FCT) which is designed to replace stereotyped or self-injurious behaviors by providing the individual with more appropriate and effective ways to act on the environment and achieve the individual's desired ends. This strategy is particularly useful with nonverbal individuals. Finally, environmental enrichment is used as a way to provide alternative response or behaviors for the individual that can be reinforced.

Definition

Stereotypies

Etymology: Gk, *stereos* + *typos* mark

Stereotypies are repetitive, persistent, non-goal, and apparently purposeless motor actions and speech patterns which are carried out in a rhythmic and uniform way that serves no obvious adaptive functioning and are not explained by other movement disorders or paroxysmal event.

It is necessary to distinguish from stereotypic behavior that is a behavior that looks unusual, strange or inappropriate, a voluntary act that occurs repeatedly in the same way and it is characteristic for that person but does not cause physical damage, therefore includes not only stereotypies but other repetitive behavior or sensory action leading to overestimated frequency compared with stereotypies.

In DSM-5, stereotypic movement disorder (SMD) is included in the neurodevelopmental section, with onset in the early developmental period, as a variety of repetitive and uncontrolled movements for a period of no less than 4 weeks that interferes with activities and may result in self-injury. DSM-5 substituted no functional by purposeless motor actions, added criteria of severity, and include specifiers if associated to self-injury, genetic, medical, and another neurodevelopmental disorders or environmental factors. The ICD-11 definition is very similar to DSM5, but SMD is distinguished from body-focused repetitive behavior disorders, such as trichotillomania and skin-picking disorders, not preceded by cognitive phenomena included under the umbrella of obsessive and related disorders.

Stereotypies usually begin in the first years of life, most of the cases before 2 years of age, the movements are paroxysmal, last for seconds to minutes, appear multiple times a day, and have a fixed pattern. The movements usually abruptly cease when the person is distracted, though they may immediately return. They are not present during the sleep, and phonation may occur during the performance. Stereotypies are usually maintained by the reinforcement of the behavior itself, described as calming and comfortable, and people affected usually does not try to stop them. Stereotypies are not associated to premonitory urge, and they are usually precipitated by overwhelming environment, sensory overload, uncontrollable emotions, thoughts, or intense imagery. They are

different from mannerisms which are unusual repeated performances of goal-directed motor actions or maintenance of an unusual modification of adaptive postures. They are also different from tics that tend to be rapid, random, and associated to premonitory urges or desires to reduce an inner tension.

Primary motor stereotypies (leg shaking, thumb sucking, nail biting, grinding) are common in typically developing children (up to 70%), whereas complex motor stereotypies (hand flapping, waving, finger wiggling, mouth opening, orofacial movements, head nodding) are much less frequent (3–4%). Primary complex motor stereotypies occur also in children without underlying disorders and usually persist along their life being the head nodding the more likely to be resolved in adult life. In typical developing children, stereotypies decrease from 2 years old, and concern arises when persist; they are very intense and frequent, appear with an atypical presentation, or interfere with functioning.

Secondary stereotypies occur associated with other disorders such as developmental disabilities, sensory deprivation or deficits (70–100% of blind people), schizophrenia, autistic spectrum disorders (ASD), genetic disorders such as Rett syndrome, Lesch Nyhan, Cornelia de Lange, Angelman syndrome, Fragile X, Williams syndrome, and Smith-Magenis syndrome, neurological disorders (tumors, Parkinson's disease, dementia, infections, autoimmune disorders, etc.), and drugs, namely, neuroleptics, amphetamines, or cocaine.

Approximately half of the people with autism present stereotypies which are more frequent at younger age, lower intelligence, and with greater symptom severity. Gender is not associated with increased prevalence. In most of cases, triggering factors are found, namely, anxiety, anger, noise, interest in objects, and visual imagery. Sometimes pleasure and anxiety occur during the stereotypies. In children with autism, stereotypies may interfere in the acquisition of new skills, functional performance, and social interaction and may be associated with stigmatization. Although stereotypies are very frequent in people with autism, they are very little understood with little knowledge of pathophysiology and treatment.

It is essential to distinguish stereotypies from other repetitive behaviors and also from tics or seizures in order to reach a better understanding of the phenomena. Although the definition of stereotypies includes to be no functional and purposeless, adolescents and adults with autism argue that stereotypies are a useful coping mechanism that helps them to regulate themselves when experiencing intense emotions, thoughts, and imagery.

Stereotypies are related to dysfunction of prefrontal corticobasal ganglia or cortico-striatal-thalamo-cortical pathways, associated with hyperstimulation of dopaminergic systems. Low level of GABA in anterior cingulate cortex and striatum and in neuroimaging studies volumetric reductions in frontal white matter have also been found.

With respect to treatment, behavior-modifying techniques, habit reversal, and differential reinforcement of other behaviors are the most frequently used treatments although pharmacological treatments are also used without a firm evidence of effectiveness. There is some evidence of parent intervention behavior therapy, with stronger effect in younger children.

Steroids

Lawrence David Scahill
 Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA
 Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA
 Department of Pediatrics, Emory University, Atlanta, GA, USA

Definition

Steroids are naturally occurring hormones in the body that carry out many important biological functions. Medications that have been developed for steroids are primarily used as anti-inflammatory

medications or hormone replacement therapy. Early case studies suggested that steroid medications could be helpful in children with autism or related developmental disabilities (Lerman et al. 1991; Stefanos et al. 1995). In addition, a case study in a child with concurrent autism and a rare autoimmune disorder condition reported remission of the developmental delays following treatment with prednisone. However, it is generally agreed that steroids are unlikely to be useful in children or adults with autism who do not have other medical conditions that require their use. Steroid medications are well known for adverse effects that are behavioral in psychiatric nature. For example, steroids can cause increased anxiety, depressed mood, or mania in some patients. This may be important in children or adults treated with steroids for medical reasons who suddenly develop psychiatric symptoms.

Stigmatization

Naomi Schneider
 College of Education and Human Ecology, The Ohio State University, Columbus, OH, USA

Synonyms

[Social stigma](#)

Definition

Stigmatization is the social disgrace or disapproval of a personal trait that goes against the norm. The label of “autism” is most stigmatizing when it is misunderstood or used to isolate individuals. For example, individuals with autism have been negatively characterized as being mentally retarded, not intelligent, and socially awkward. Parents of children with autism were incorrectly characterized as having poor parenting skills or not loving their child. These characterizations have led to social isolation and rejection. Fortunately, the stigma or disapproval for autism is decreasing as people learn more about the disorder.

[Psychostimulants](#)

Definition

Stimulants, also called psychostimulants, are medications that enhance dopamine and, to a lesser extent, norepinephrine in the brain. The two most common classes of stimulants are methylphenidate and amphetamines.

Amphetamine: Amphetamines are stimulant medications that enhance the release and block the reuptake of dopamine in the brain. Taken at large doses, this mechanism of action can produce euphoria and increased energy. Because of these effects, amphetamines are subject to abuse. In doses used to treat attention deficit/hyperactivity disorder, however, these stimulant effects are not usually present. The enhanced release of dopamine is presumed to be the source of improved attention and decreased activity.

Amphetamines are associated with many adverse effects that are relevant to children and adults with autism. For example, they can cause insomnia, decreased appetite, increased stereotypic behavior, and irritability. To date, the amphetamines have only been evaluated in small studies in children with autism with equivocal results. It appears that the potency of the amphetamine compounds makes it difficult to find a dose that is helpful, but not associated with dose-limiting adverse effects.

Methylphenidate: Methylphenidate is also a stimulant medication. Although methylphenidate also enhances release and blocks the reuptake of dopamine, it is less potent than the amphetamines. There are many preparations with methylphenidate including immediate-release compound in which the tablet is rapidly absorbed and the duration of action is approximately 4 h. When using the immediate-release compounds, it is likely that the dose will have to be repeated twice or even three times per day. There are also long-acting formulations marketed under several different trade names. These long-acting formulations do not have to be repeated throughout the day. However, various products may only come in particular strengths. Therefore, becoming familiar with the different brands of medications is important for using these long-acting formulations of methylphenidate in the clinic. Methylphenidate also comes in a transdermal skin patch. The skin

patch can be worn for 8–9 h per day and replaced with a new patch each day. The skin patch comes in several strengths and may require some trial and error to achieve comparable dosing with oral forms of methylphenidate. One drawback of the current skin patch preparation is the relatively high cost.

The immediate-release formulation of methylphenidate was studied in a large-scale, multisite trial in children with autism spectrum disorders (Research Units on Pediatric Psychopharmacology 2005). The study included three doses of methylphenidate (low, medium, and high) and placebo in a crossover trial (each subject received the study treatments in random order under double-blind conditions). All active doses of methylphenidate were superior to placebo in this short-term study. In contrast to the benefits observed in typically developing children with attention deficit/hyperactivity disorder, however, the beneficial effects were modest in children with autism spectrum disorders who were hyperactive, impulsive, and distractible. Furthermore, the study showed that methylphenidate doses that are well tolerated in typically developing children with attention deficit/hyperactivity disorder were less well tolerated in children with autism spectrum disorders. Intolerable adverse effects included irritability, insomnia, loss of appetite, and increased stereotypic behavior. These results suggest that when treating children with autism spectrum disorders accompanied by hyperactivity and impulsiveness, the low-to-medium dose range is likely to produce modest benefit. However, attempts to achieve a greater benefit by pushing the dose upward are likely to encounter dose-limiting adverse effects.

Synonyms

[Sensory stimuli](#)

Definition

A stimulus is defined as an environmental event that affects an individual's behavior through their sense modes, such as vision, hearing, smell, taste, touch, kinesthesia, and balance. Additionally, events such as dreams, mental images, and hallucinations are also considered stimuli and may affect behavior; however, these do not activate a specific sense mode. This makes their study and detection more difficult. Stimuli are dynamic and often studied in terms of stimulus changes in the environment, such as a light turning on or off or a sudden loud noise. Stimuli can also be the effects of internal bodily events such as the onset of a toothache, stomach pangs, and dizziness.

Stimuli are important components of a variety of autism treatments. They can be used to provide the context for behavior to be expressed or

withheld, delivered as prompts during learning trials, and – when overselected (as defined below) – can even interfere with learning. In this regard, these stimuli are called antecedents because they happen before the behavior of interest.

A phenomenon termed “stimulus overselectivity” (Lovaas et al. 1971) is often discussed in relation to individuals with a diagnosis of autism. Research has shown that when presented with a complex stimulus, individuals with autism may attend only to certain components of the stimulus (which may be irrelevant to the appropriate response). An implication of stimulus overselectivity is that many individuals with autism have difficulty in learning situations, requiring them to attend to more than one component of a stimulus (i.e., an instruction to put on a blue shirt).

In addition to its role before responding occurs, a stimulus can also influence behavior by following it. When this happens, the stimulus is called a consequence and can serve as a reinforcer or punisher. The use of certain stimuli both before and after the desired responding has been central to applied behavior analytic interventions aimed at enhancing learning, decreasing behavior problems, and improving quality of life for people with autism.

Stimulus Control

Shaunessy Egan and Roseann R. Groh
Center for Children with Special Needs,
Glastonbury, CT, USA

Synonyms

[Discrimination](#); [Discrimination training](#); [Discriminative stimulus](#)

Definition

Stimulus control refers to the emission or suppression of a behavior contingent upon the presence or absence of a stimulus. Therefore, behavior is said to be under stimulus control when that behavior occurs more often in the presence of certain antecedent stimuli and does not occur in the absence of the same antecedent stimuli. When a behavior is under stimulus control, the frequency in which the behavior is emitted may be altered. Other measurable dimensions of behavior may also be affected in the presence of the stimulus such as latency to responding, the duration of the response emission, or the intensity in which the behavior is emitted. When a new skill is being taught, prompting hierarchies may be employed to evoke responding in the presence of the correct stimulus and not in the absence of that stimulus. A transfer of stimulus control occurs when those prompts are faded over time, and the behavior is emitted in the presence of the stimulus alone, without supportive prompts in place, and when the behavior does not

occur in the absence of that stimulus. For example, a person is taught to pick up the phone and say “Hello” when the phone rings, and they are taught to suppress the behavior of picking up the phone and saying “Hello” in the absence of the phone ringing.

Stimulus Overselectivity

Jessica Bradshaw
Clinical Psychology, UCSB Koegel Autism
Center, University of California, Santa Barbara,
Santa Barbara, CA, USA

Definition

Stimulus overselectivity is an attentional abnormality common to individuals with autism spectrum disorder characterized by hyper-attentiveness to selected stimuli in the environment and lack of attention to other relevant stimuli.

Various behavioral and cognitive theories offer explanations for this particular phenomenon.

A behavioral perspective put forth by Lovaas, Schreibman, Koegel, and Rehm (1971), explains stimulus overselectivity as a narrowing of attention to a particular characteristic of a single stimulus or to distinct stimuli in a complex environment. Other authors have related this concept to the term “tunnel vision” (Rincover and Ducharme 1987). The sensory overload hypothesis, another possible explanation for overselectivity, posits that children with autism become overloaded with sensory input and therefore can only attend to a limited amount of sensory information at a given time. Alternatively, cognitive theories suggest that this phenomenon is the result of a generalized attentional bias in visual perception (such as a more detail-oriented style of information processing) in which they are unable to extract context-dependent relevant features from the stimuli or the environment (Hermelin 1976). Treisman (1969) suggested that such a phenomenon might occur if a child failed to switch attention between multiple cues. Stimulus overselectivity is not unique to autism spectrum disorders and has been observed in individuals with intellectual disability as well (Dickson et al. 2006; Wilhelm and Lovaas 1976).

In intervention settings, stimulus overselectivity can impact how the child learns new skills. For example, children with autism have been observed to fail to generalize newly learned skills across novel settings and individuals outside of the original treatment context (Rincover and Koegel 1975). Additionally, if this strategy of processing and responding is not addressed early in treatment, progress in the areas of social behavior and language acquisition can be limited (Rosenblatt et al. 1995). For this reason, some interventions have identified responding to multiple cues as a pivotal area that, if targeted, can have widespread effects on many areas of functioning (Koegel et al. 1999).

Definition

In typical development, narrative skills progress from simple descriptive sequences to more complex and elaborated episodic structures. A story structure decision tree is a graphic tool for guiding the narrative analysis of children’s stories. The decision tree is a flow chart containing a series of yes or no questions. Each “yes” answer moves the user to the next question/level, while a “no” response prompts the user to exit the flow chart whereby the child’s level of story grammar development is indicated. For an example, see Westby’s (2005) Story Grammar Decision Tree based on Stein and Glenn’s (1979) classic description of story grammar.

Strabismus

Oana De Vinck

Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

Synonyms

[Cross eye](#)

Definition

Strabismus refers to misalignment of the eyes typically due to a lack of coordination between the extraocular muscles, which prevents bringing the eye gaze of each eye to the same point in space, thus preventing binocular vision. This will most notably affect stereopsis or depth perception and can have serious consequences with 30–50% of children with strabismus developing amblyopia or vision loss. Strabismus is one of the most common eye problems in children and affects about 4% of children less than 6 years of age. Strabismus can occur in one or both eyes and in any direction. For example, in esotropia, there is inward deviation of the nonfixing eye, and in exotropia, the nonfixing eye outwardly deviates. Strabismus is also classified based on time of onset, such as infantile, acquired, or secondary to another pathological process, such as cataract. Strabismus must be treated early in order to decrease the risk of amblyopia, maintain binocular vision, and minimize the psychosocial effects of looking different than one's peers. Treatment depends on the etiology and may involve a combination of eyeglasses, vision therapy, and

surgery, depending on the underlying reason for the misalignment.

Stranger Anxiety

Tina R. Goldsmith

Center for Development and Disability,
University of New Mexico, Albuquerque, NM,
USA

Definition

Stranger anxiety, which typically involves an overt display of mild to moderate emotional distress, is identified by observing how infants respond to the approach of an unfamiliar adult. Demonstration of signs of anxiety, or wariness, in response to an approaching stranger is a significant, universally observed, adaptive response that occurs in the course of typical child development. Although there is significant individual variation in the onset and severity of stranger anxiety, it is rare to observe such wariness during the first 6 months of life. However, by 8 months, stranger anxiety is commonly observed, and the phenomenon peaks around 12 months. Some factors that may influence stranger anxiety are temperament and attachment. Fussy, insecurely attached infants are more likely to respond negatively to the approach of a stranger, as compared to easy going, securely attached infants. Additionally, it is important to note that stranger anxiety is also influenced by a range of contextual factors, including whether or not the caregiver is present, the physical characteristics of the approaching stranger, the rapidity with which the stranger approaches, the physical positioning of the child during the approach, and the familiarity of the setting. Although individual differences impact the presentation of stranger anxiety, research suggests that children with autism do indeed display signs of stranger anxiety over the course of their development.

Strong Narrative Assessment Procedure (SNAP), Second Edition

Yu Han

Neuroscience, University of Vermont,
Burlington, VT, USA

Synonyms

[SNAP](#)

Description

The Strong Narrative Assessment Procedure (SNAP; Strong 1998) is an individually administered criterion-based method to measure various skills related to narrative discourse. Children from kindergarten to 8th grade are the appropriate candidates to be administered the SNAP. The SNAP assessment is divided into multiple steps; children recall relevant details of stories, summarize the stories, and answer questions that assess comprehension of the stories following specific instructions. Flexibility in transitioning between verbal and written language is required by students who are administered the SNAP. The ultimate goal of this assessment is to provide an approach to treatment that will support children when engaging in positive social interactions.

Although the targeted age groups for the SNAP procedures are children aged 6–13 years, comparison data are available only for children aged 7–10 years. SNAP is administered using tape recordings as well as corresponding wordless picture books: *Frog, Where are You?* (Mayer 1969), *Frog Goes to Dinner* (Mayer 1974), *A Boy, a Dog*

and a Frog (Mayer 1967), and *One Frog Too Many* (Mayer and Mayer 1975). The book *Frog Goes to Dinner* (Mayer 1974) is administered as a sample test that does not impact the final narrative score. The instructor then administers one of the remaining stories to elicit a sample narrative. The child is asked to listen to the audiotaped narrative while simultaneously looking at the accompanying wordless picture book. The manual suggests that the instructor should create a receptive environment for taking the SNAP by asking the child to listen to the stories through headphones or by the instructor leaving the room to allow the child to focus on the story (Rathvon 2007). After this step, the child is asked to retell the story and answer the 10 questions probing comprehension of the story (five factual and five inferential questions). When retelling the stories, the child is not permitted to use the picture books for assistance. Both the narrative and the responses of the child to the comprehension questions are recorded and transcribed.

Once the child's oral responses are transcribed into written form, the narrative sampling procedure is implemented by the instructor to identify "C-units" (Ward 2007). C-units consist of a main clause, modifiers, and any subordinating clauses. For example, a complete sentence such as "The boy was riding his bike on the street" is a C-unit. Narrative length is determined by counting the total number of words in a C-unit. Each C-unit is used to evaluate cohesion, syntax, grammar, and fluency in literacy (Ward 2007). Fluency is assessed by the total numbers of pauses per C-unit and determines whether self-corrections or abandoned utterances interfere with the child's retelling of the stories. Cohesion refers to linguistic components (e.g., grammar or vocabulary) used by a child to make connections among the sentences in the stories. For instance, conjunctions (e.g., and, but, or) are cohesive elements which connect and create fluency between a series of phrases and simple sentences. The SNAP manual provides examples of cohesive elements which can be administered. Lastly, syntax, i.e., the rules for constructing sentences, is assessed by counting the total number of clauses used in the stories (e.g., subordinate, adverbial, or nominal).

After these linguistic elements are analyzed, the story grammar components of a child's narrative stories are evaluated. Story grammar components are the specific elements that are universal to a narrative. These include information about setting, initiating events, internal responses, attempts to solve problems, and consequences of the stories. The initiating events refer to problems in the stories. For example, "the boy ran over a nail with his bike and got a flat tire" is an initiating event. The initiating events prompt internal responses from the character(s) in the stories. The internal response to the initiating event will be "the boy was very angry that his tire was flat." The initiating event induces attempts/plans to solve the problem. "The boy tried to fill the hole with a piece of gum" is a possible attempt to solve the problem caused by the initiating event. This plan/attempt may not work, leading to a second attempt at fixing the problem. Each narrative is also expected to include the consequence of the attempts. In this story, "the boy fixed the bike so that he was able to ride home" is the consequence of the attempts.

The instructor scores the child's responses to the story comprehension questions. These responses are determined to be either accurate or inaccurate based on the instructor's perspective. The SNAP manual provides instructions to convert a child's raw scores to frequency and percentage of narrative elements. Average scores for children ages 7–10 years are provided as normative data for comparison (Rathvon 2007). A score that falls more than one standard deviation below the mean is considered "inadequate." Means and standard deviations are provided in the manual to interpret the comprehension responses for children who are only 7 years old. Guidelines for scoring and interpreting the comprehension questions included the information for children who are not just 7 years old. However, empirical evidence is not provided to support children beyond 7 years of age (Ward 2007).

Historical Background

Carol J. Strong developed SNAP with the purpose of assessing the narrative skills of children with

language impairments (LI). These children normally demonstrate shorter narratives, more grammatical errors, fewer cohesive devices, and fewer story grammar elements compared to neurotypical children (Swanson et al. 2005; Ukrainetz and Gillam 2009). Although SNAP was originally designed for testing children with LI, it also is utilized to test children with Autism Spectrum Disorder (ASD) who perform poorly in narrative discourse. Research shows that children with ASD produce shorter narrative discourse with fewer connections between related events compared to neurotypical children (Tager-Flusberg 1995). Moreover, oral statements from children with ASD are less complex and syntactically correct (Capps et al. 2000).

In 1988, SNAP was field tested for the first time using samples of neurotypical children ($N = 39$) and children with LI ($N = 39$) ages 8–10 years. The collected narrative samples were analyzed to establish the stability of story length and cohesive adequacy over time (Strong 1989; Strong and Shaver 1991). Strong (1998) received funding from the ASHA foundation and Utah State University to reanalyze the previous samples for fluency, syntax, and story grammar. In 1998, additional data were collected from children aged 7 years ($N = 26$). These data were published in the SNAP manual for comparison purposes.

Psychometric Data

The SNAP test was first implemented in 1988. It collected and analyzed 312 narrative samples obtained from 39 neurotypical children and 39 children with LI, all between 8 and 10 years of age. Another sample included 13 typically developing children and 13 children with LI, all 7 years old. As the sample sizes are not deemed statistically adequate, the data should be evaluated with a caution. Moreover, the participants in the study were limited by geographical homogeneity as all were from the State of Utah.

Measurements of interrater reliability were obtained for both sample groups regarding agreement on transcription of the 312 narrative samples in the 1988 study. There was complete agreement

(i.e., 100% accuracy) over 64% of the total transcript and no more than a three-word disagreement over the remaining 36% of the transcripts (Strong 1998). There also was 99% agreement in Interrater reliability for segmentation of a selected number of transcripts (Strong 1998). For the sample year 1998, interrater reliability of transcription, segmentation, and coding was greater than 90% for all measurements (Strong 1998). In an independent investigation, John et al. (2003) reported interrater reliability for segmentation and coding of transcripts as 81% and 87%. No evidence of test-retest reliability is provided.

There is some evidence supporting the validity of SNAP. Construct validity was administered by comparing mean scores of the groups of neurotypical and language-impaired sample students. In the 1988 sample, only 62% of scores were significantly different between groups, and in the 1998 sample, only 54% of scores were statistically significant (Strong 1998). These results show that SNAP reliably differentiated between neurotypical children and language-impaired children. When children with ASD ($N = 17$) were compared to typically developing children, the groups did not differ on narrative length, semantic and syntactic measures, cohesion, clause development, story grammar, or number of complete episodes (Young et al. 2005). However, the groups did differ in their ability to answer the inferential comprehension questions. Criterion-related validity was not investigated.

By comparing test scores over time, the SNAP manual indicates that the four stimulus stories are equivalent in length, syntactic measures, complexity, cohesive density, and story grammar complexity (Strong 1998). John et al. (2003) found that participants ($N = 61$) showed highest accuracy in retelling the story *A Boy, a Dog and a Frog* (Mayer 1967). Moreover, when the scores of the other two stimulus stories were compared, the comparison of the scores were inferential (the book *Frog, Where are You?* (Mayer 1969) was not included in this analysis due to the sample story). John et al. (2003) suggested that clinicians may want to use *A Boy, a Dog and a Frog* (Mayer 1967) as the practice narrative and use the other three stories for test-retest purposes.

Clinical Uses

The ability to engage in narrative discourse is important for development. Competent use of narrative is critical both for assessing and engaging in social communication. Personal narrative is used on a daily basis to share details of events and other information with others. Narrative use is a pragmatic skill reflecting how an individual uses language in a social context. A speaker, when telling a story, should be able to recognize a listener's knowledge level and comprehension ability. Moreover, he/she should notice nonverbal cues indicating whether the listener appropriately understands the conversation, is bored, or is confused by the communication. Therefore, successful storytelling requires understanding of the perspective of the listener as well as understanding of other social communication skills of the listener.

As previously discussed, children with ASD demonstrate deficits in narrative discourse compared to same age neurotypical peers, especially regarding understanding another's perspective. Theory of Mind (ToM) is the theoretical basis for many interventions designed to improve the ability to understand another's perspective (for a review, see Baron-Cohen et al. 1993). Theory of Mind techniques help children with ASD to acknowledge that people feel and think differently from one another. Children with ASD have difficulty interpreting other people's facial expressions from various social contexts and situations and, as a result, have significant deficits in social interactions. For example, they often lack empathy towards others. These deficits are related to irregular activity within the amygdala and ventromedial prefrontal cortex (vmPFC) of the brain. In addition, these deficit factors are related to inadequacy in narrative discourse. For instance, there is a positive relationship between children's performance on a standard measure of ToM and their frequency of recognizing a character's thoughts and emotions from the narrative stories (Capps et al. 2000; Tager-Flusberg and Sullivan 1995). Children with ASD have poor scores in ToM and a relative inability to interpret the character's emotional details from the stories. Moreover,

children with ASD have lower linguistic skills which contribute to poor performance in storytelling. The poor quality of their storytelling is reflected mainly in their use of simple structure with limited cohesive devices and other literate language features that control to the quality of the story (Strong 1998).

Narratives are integral aspects of social communication and with a fundamental role in developing meaningful relationships with others. Thus, the assessment of narrative competency is important for children with ASD. SNAP was structured to identify areas of concern in narrative discourse in order to guide intervention goals and monitor progress over time. Understanding narrative language is related to an empirical behavioral foundation in children with ASD. Although the SNAP is one method to assess narrative language use in children with ASD, the sample sizes in SNAP studies are too small to provide accurate measures of reliability and validity. The SNAP might be appropriate to use in conjunction with a norm-referenced measure, such as the *Test of Narrative Language* (TNL; Gilliam and Pearson 2004).

Structured Behavioral Interventions

Leona Oakes

Department of Clinical and Social Sciences in Psychology, University of Rochester, Rochester, NY, USA

Definition

Structured behavioral intervention is an umbrella term for interventions in which the therapist or teacher organizes the learning environment, selects the activity, and directs the individual with autism. Structured behavioral interventions are often implemented in a one-to-one setting

between a trained therapist and child. The therapist provides a clear cue or antecedent to initiate the desired behavior from the individual and uses positive reinforcement to strengthen the occurrence of the behavior following the antecedent. Often structured behavioral interventions are based on a breakdown of tasks into their component steps with a set plan for linking the steps together as the child masters each step and is gradually moving to more complex tasks. Structured behavioral interventions are often described as “didactic” and are contrasted with interventions in which the therapist follows the child’s lead and aims to expand on activities that the child initiates. Many school- and home-based programs are considered to be structured behavioral interventions, among which approaches based on applied behavioral analysis (ABA) are the most common.

Historical Background

Structured behavioral interventions began to be used in the education of children with autism spectrum disorders in studies on ABA conducted in the early 1960s. These initial studies incorporated experimenter-led tasks showing that children with autism could learn new skills if they received systematic instruction. In the mid-1960s, investigators demonstrated that similar procedures could be implemented in clinical settings and developed an instructional format now called discrete-trial training (DTT). DTT consists of small units of instruction implemented by a teacher in a one-to-one setting with a child. These units of instruction are composed of a cue, prompt, response, consequences, and intertrial interval. For example, in a DTT session aiming to enhance imitative behavior, the instructor would give a verbal cue “Do this” and visual cue (taps head), perhaps with a prompt such as lifting the child’s arm up to elicit the behavior and reinforce the child for displaying the desired behavior.

Other examples of structured behavioral interventions include (1) task analysis and chaining in which complex skills are broken down into their component steps to be taught individually and

then strung together and (2) script training, which focuses on using words, pictures, videos, or live models to show a sequence of appropriate social and verbal responses. Structured behavioral interventions have been implemented in individual and group formats in a range of settings, such as home-based intervention programs, specialized schools, and integrated classrooms.

Rationale or Underlying Theory

The use of structured behavioral interventions is based on the view that individuals with autism require didactic, systematic instruction because they are unable to learn in the same ways young typically developing children learn (e.g., playing creatively and interacting with others) and often have little interest in doing so because they are unresponsive to social reinforcement (e.g., verbal praise from parents). Structured behavioral interventions involve carefully prompting and reinforcing successes and providing instruction at a rapid pace in order to provide many learning opportunities and teach a wide range of skills efficiently.

Goals and Objectives

Structured behavioral interventions aim to place an individual with autism in an environment that optimizes the rate of learning and promotes the individual’s experiences of success. This is done by breaking complex tasks into component steps that can each be taught and built upon (e.g., identifying the steps involved in a task such as toothbrushing and teaching each task separately).

Treatment Participants

People with autism of any age are candidates for a structured behavioral intervention as long as a motivating positive reinforcer can be identified. Research suggests that the younger a participant starts in the intervention, the more significant are his or her improvements.

Treatment Procedures

A number of interventions are considered to be structured behavioral interventions, so specific treatment procedures vary by intervention. As a therapist- or teacher-led intervention, procedures are usually implemented in a one-to-one setting. Generally, each behavioral instruction is cued by a specific antecedent and followed by a consequence designed to either reinforce a correct response or extinguish an incorrect response.

Efficacy Information

Numerous single-case studies indicate that structured teaching approaches such as DTT, task analysis/chaining, and script training can be effective. Early intensive behavioral intervention (EIBI) programs that emphasize such methods (such as the Ivar Lovaas's UCLA You Autism Project) have also reported high success rates such as significant increases in IQ test scores, Vineland adaptive behavior scale scores, and integrated classroom placements.

Outcome Measurement

In single-case studies of structured behavioral interventions, outcome is usually measured by repeated, direct observations of changes in the rate of a specific target behavior, such as an increase in the display of a language skill or a reduction in an aberrant behavior. In EIBI studies, outcome measures usually include standardized tests of intelligence and adaptive behavior.

Qualifications of Treatment Providers

Structured behavioral interventions may be implemented by a variety of treatment providers, such as paraprofessionals, educators, and residential care providers. The interventions are often delivered under the supervision of a behavioral analyst.

Visually organized learning environments

Definition

Learning environments are organized so that the curriculum (activities, schedule, physical environment) is clearly visually communicated to both the students and educational personnel (Iovannone et al. 2003). Structured environments have been demonstrated to be an essential part of programming for students with autism spectrum disorders (ASD) (Bodfish 2004; Iovannone et al. 2003; Mesibov and Shea 2010). Structured classrooms for students with ASD utilize the principles of Structured Teaching (an evidence-based approach devised by the TEACCH [Treatment and Education of Autistic and related Communication-handicapped CHildren] Program in North Carolina; Mesibov and Shea 2010).

Key features of structured classrooms are (Ball n.d.; Mesibov and Shea 2010; Mesibov et al. 2004):

- Physical structure – using furniture to demonstrate expectations and reduce distractions.
- Visual schedules – using objects, pictures, or the written word to show the student the sequence of events.
- Visually structured individual tasks that incorporate object, picture, and/or written instructions.
- Organizing a sequence of individual tasks using visual work/activity systems – using objects, pictures, letters, numbers, or the written word; tasks are organized to show the student what they have to do, how many tasks they need to do, how they are progressing,

when they will be finished, and what they are going to do next, for example, lining up the tasks on the students' left and having them move them to their right when completed.

- Using students' relative strengths to support weaker skills. For example, requiring a student to select a picture of the weather (utilizing strong visual skills) during a verbal discussion about the weather (thus supporting relatively weak verbal communication skills).
- Using students' special interests to increase engagement in learning. For example, teaching counting by having a student interested in trains count the number of train cars.
- Strategies to increase students' meaningful, spontaneous communication. For example, teaching a nonverbal student to hand the instructor a cup to request a drink.

Within these features of a structured classroom, the key to student success is that each is individualized according to the strengths and weaknesses of each student (Mesibov et al. 2004).

[SDA](#)

Definition

A structured descriptive assessment (SDA) uses principles of applied behavior analysis to describe the causes and consequences of a given behavior. A SDA typically occurs in the child's natural environment (e.g., the child's classroom) with no manipulation of environmental variables. The examiner records the antecedent of the child's behavior, target behavior, and consequence. For example, if the child might be engaging in self-harm, the examiner will record the antecedent of this behavior (e.g., the teacher asking a difficult question to the child), the child's behavior (e.g., biting of his hand), and the consequence (e.g., the child is sent out of the classroom with his aide). This type of assessment is often used to determine the cause of maladaptive behavior. It differs from functional behavior analysis as the examiner does not control for environmental variables.

Definition

Structured teaching (often associated with the Treatment and Education of Autistic and Related Communication-Handicapped Children [TEACCH] method) refers to strategies that promote systematic and predictable instruction that supports individuals with autism spectrum disorders to better understand their environment and live in it more independently. Structured teaching provides an environment that is organized with clear concrete visual information that defines the environment. Structure is provided by the adults, the physical organization of the environment, materials, and routine. It is important to

conceptualize that the structured teaching is not faded or removed over time if adjusted to meet the changing needs of the individual with autism spectrum disorder.

The components of structured teaching relate directly to the characteristics of autism spectrum disorder. Many individuals with autism spectrum disorder are visual learners, and structured teaching relies heavily on visual supports. Effective processing of information is often a challenge for individuals with autism spectrum disorders, and structured teaching highlights routines, beginnings, and endings. Attention and sensory deficits impact how individuals with autism spectrum disorders learn, and structured teaching ensures that the environment is modified to reduce distractions and excessive stimulation. Structure teaching benefits individuals with autism spectrum disorder by reducing anxiety through predictability, it increases learning through rule-based strategies, and it promotes independence by encouraging reliance on the system rather than people.

Structured teaching is an effective lifelong tool that capitalizes on organizing the individual with autism spectrum disorder's world, through organizational and temporal structure.

Definition

Evidence-based treatments for children with autism spectrum disorder (ASD) include behavioral interventions that teach communication, cognitive, social, and adaptive skills. One-to-one instruction is a critical component of evidence-based instruction for students with ASD, but is not used as often as recommended. Two recent studies suggest that student characteristics may affect teachers' decisions to select types of one-to-one treatment (e.g., pivotal response training [PRT] vs. discrete trial training [DTT]) and implement them in the classroom. In the first, teachers reported choosing DTT for students who had more significant cognitive delays, who struggled with compliance, and who did not imitate or attend in less structured settings (Stahmer et al. 2005). In the second, children's higher sensory symptoms, lower social approach, lower verbal skills, and higher self-regulation difficulties were found to be associated with more frequent 1:1 instruction (Nuske et al. 2019).

Historical Background

There has been a steady rise in the number of children receiving ASD intervention services through schools (U.S. Department of Education

2017), but the type and intensity of treatment vary greatly (White et al. 2007). There is little research on factors that predict the type and intensity of school-based treatment children with ASD receive. Such factors may include different school resources, such as staffing, or teacher characteristics, including teacher preferences, training, pedagogy, and skill (Stahmer et al. 2005). Some studies have found associations between these characteristics and use of behavioral interventions for children with ASD (Hogan et al. 2015), but others have found no association (Segall and Campbell 2012; Morrier et al. 2011; Mandell et al. 2013; Stahmer et al. 2015).

Variability in treatment delivery also may be driven by child characteristics (Stahmer et al. 2005), such as their language level, severity of ASD symptoms, or regulatory difficulties, all of which may consciously or unconsciously drive teachers' decisions about who is best suited for one-to-one (1:1) instruction or a particular type of treatment. The authors have found that child characteristics account for about half of the variance in the frequency with which children received 1:1 intervention in school (Lushin et al., under review), but that study did not investigate whether specific child characteristics are associated with teachers' decisions to provide 1:1 intervention.

Related research has examined whether child characteristics predict outcomes as a result of different types of treatment. Two evidence-based treatment approaches for children with ASD include DTT (Lovaas 2003; Lovaas and Buch 1997) and PRT (Schreibman et al. 2015). Both DTT and PRT are based on principles of applied behavior analysis (ABA; e.g., operant conditioning, systematic reinforcement; Ringdahl et al. 2009; Smith and Iadarola 2015) and are administered by an adult working 1:1 with a child. A key difference between these two approaches is that DTT is adult-directed and incorporates external reinforcement (e.g., token reward for play initiation), while PRT is child-directed and incorporates naturalistic reinforcement (e.g., smiles/engagement for play initiation; Koegel et al. 1999a, b). Both DTT (Anderson et al. 1987; Lovaas 1987; McEachin et al. 1993) and PRT (Koegel et al. 1999b; Nefdt et al. 2010) are effective practices

for children with ASD. Research has indicated that DTT is most effective when implemented in combination with naturalistic interventions to facilitate generalization of skill development across settings and support the development of spontaneous behaviors, such as play initiation (Duffy and Healy 2011; National Research Council 2001; Schreibman et al. 2015; Smith 2001).

Children who made the greatest gains through DTT demonstrated greater social engagement (social approach, joint attention, and imitation), were younger, and had a higher IQ (Smith et al. 2015). Children who made the greatest gains through PRT were younger (Baker-Ericzén et al. 2007), had higher social approach, and had higher expressive language ability (not overall IQ). They also had higher positive affect and appropriate toy contact and lower stereotyped/repetitive vocalizations (Fossum et al. 2018). Research by Schreibman and colleagues suggests that the profile of children who made greater gains with PRT was not the same as those who responded most to DTT (Schreibman et al. 2009; Sherer and Schreibman 2005), indicating utility in identifying unique responder profiles for different treatments. Among children with ASD who received a comprehensive program that incorporates DTT and PRT, fewer self-regulation difficulties over the course of the academic year were associated with higher cognitive skill gains (Nuske et al. 2017). This body of work has therefore identified some overlapping and some unique child characteristics of higher responders to DTT and PRT.

Such research could be used to inform a personalized medicine approach (i.e., individual tailoring of treatment) for children with ASD, by selecting interventions for a child based on their characteristics or behavioral profile (Masi et al. 2017; Ousley and Cermak 2014). Personalized medicine approaches have been recently applied to clinical psychology, so to increase the efficacy of behavioral and cognitive treatments (Drake et al. 2009; Fisher 2015; Jeon and Fava 2015; Kasari et al. 2014; Lei et al. 2012; Ng and Weisz 2016). Individualizing treatments may result in better outcomes. These approaches bring new methodological considerations and challenges

and necessitate research designs that allow for treatment individualization via systematized trial and error, for example, in the case of adaptive, sequential, and crossover designs (for review, Lillie et al. 2011). Importantly, individualization may be most effective when completed a priori to starting treatment. This approach entails selecting treatments based on children's behavioral profile *before* treatment or programming begins, so to potentially avoid spending time using treatments or components of treatments that are not suited to a particular child.

Teachers may be using this approach already, either from reading of the research or from their own experience, when deciding which intervention to use with which children. Indeed, teachers note that individualizing instruction based on a child's strengths and weaknesses is critically important (Stahmer et al. 2005).

Current Knowledge

Teachers report choosing DTT for students who have more significant cognitive delays, who struggle with compliance, and who do not imitate or attend in less structured settings (Stahmer et al. 2005). This study established that teachers do factor in students' characteristics when deciding for whom to implement 1:1 instruction. However, due to the qualitative design of the study, the study was unable to empirically test whether frequency of treatment delivery and teacher selection of treatment approach relate to their students' characteristics. The second study by Nuske et al. (2019) explored this question by quantitatively examining the associations between child characteristics and teacher selection and frequency of use of PRT and/or DTT with children with ASD in their classrooms. Based on the study by Stahmer et al. (2005), researchers hypothesized that teachers would be more likely to use DTT with children who had more severe ASD symptoms, lower cognitive skills, and higher regulatory difficulties. Based on prior research regarding PRT outcomes (Schreibman et al. 2009; Sherer and Schreibman 2005), researchers hypothesized that children with higher social and semantic

pragmatic skills and higher verbal ability would be more likely to receive PRT. Researchers also explored associations with sex and race and described the variability in use of DTT and PRT across children and classrooms.

Results from Nuske et al. (2019) showed that teachers reportedly provided more 1:1 instruction in general to children who have more sensory and self-regulation difficulties, lower verbal skills, and less social approach. Findings suggest that teachers give more treatment to children with more obvious impairments. This is encouraging as it suggests that teachers are tapping into some key observable difficulties of particular children and reportedly allocating 1:1 instruction resources from their classrooms accordingly (Linstead et al. 2017). Previous research has shown that children with more significant impairments make the fewest gains in any treatment (Fossum et al. 2018; Smith et al. 2015; Thurm et al. 2007). Therefore, teachers with more severely impaired students face significant challenges in fostering positive outcomes for their students. The results show that teachers are attempting to address these students' needs by providing them with more individualized intervention.

In the context of limited classroom resources (e.g., time, space, availability of teacher aids), teachers are using 1:1 interventions to treat children who demonstrate the most obvious need. While promising in one sense, it also means that other children may be inadvertently neglected, though they may still benefit from 1:1 treatment. All children in autism support classrooms have an educational classification of ASD, meaning that their school teams have identified significant support needs consistent with ASD. However, those who are easier to manage or who have, relatively speaking, more skills are not receiving potentially beneficial treatment as other children with ASD, though they may have significant developmental delays relative to their typically developing peers. Given that for many children the bulk of their services are received through school, this may mean that many children with ASD are not receiving the 1:1 instruction that they need.

In Nuske et al. (2019), age was not associated with implementation of 1:1 instruction. These

findings suggest that teachers are not considering students' age when implementing either PRT or DTT. In the context of findings of higher positive outcomes in PRT or DTT for younger children with ASD (Baker-Ericzén et al. 2007; Smith et al. 2015), this suggests again that teachers are making decisions preferentially based on perceived students' support needs.

Findings from Nuske et al. (2019) also suggested that teachers did not differentially use DTT or PRT based on child characteristics, despite the theoretical notion that different profiles of children may be better suited to one over the other (Vivanti 2017). Evidence suggests that matching children with ASD to certain treatment styles based on their pretreatment behavioral profile may support positive outcomes (Schreibman et al. 2009; Sherer and Schreibman 2005). However, researchers found the same student characteristics predicted teachers' use of DTT and PRT. Given that the ASD field, as well as the mental health field in general, is moving toward a personalized medicine approach to treatment (i.e., to individualize treatments decision based on individual behavioral profiles; Drake et al. 2009; Jeon and Fava 2015; Ng and Weisz 2016; Stahmer et al. 2011), these results provide important insights into the current state of affairs regarding teachers' decisions about their students' educational programming. The results show that teachers are not reportedly using one treatment type more frequently over the other with children with different characteristics. The research on pretreatment behavioral profiles and optimal treatment fit is promising, but has only recently begun; therefore, further work is needed before teacher consultation models around child-treatment fit can be developed.

Future Directions

First, given that both of the studies on the association between the characteristics of children with ASD and teacher implementation of evidence-based practice rely on teacher's own report of 1:1 instruction use, these data are subject to the social desirability bias, in that teachers may have

reported higher frequencies than were actually implemented. However, this may not differentially apply to children of certain characteristics. Nevertheless, observation methods would have strengthened the measurement of intervention implementation and is recommended for future research.

Second, in Nuske et al. (2019) while ASD symptoms were measured via teacher report, cognitive and language abilities and self-regulation difficulties were measured by study staff. Therefore the latter may not have necessarily mapped onto teacher's own perspectives of children's cognitive and language abilities and self-regulation difficulties and decisions regarding the frequency with which teachers should use 1:1 across different children in their classroom. Notably, however, lower verbal skills and higher self-regulation difficulties were found to be associated with more frequent 1:1 instruction in Nuske et al. (2019). Still, future research should incorporate teachers' measures of cognitive and language abilities and self-regulation difficulties to further investigate this issue.

Third, the extent to which teachers' decisions to use treatments for more severely impacted children were well-informed or considerate of individual student needs was not specifically examined in this study. Future work could identify factors such as the extent to which cognitive biases, intentions, and adherence to coaches' recommendations affect teachers' use of 1:1 intervention.

Finally, since research in this area has just begun, it is not yet known how these findings apply outside of school or community early intervention provider settings. Future research should involve providers across a range of treatment settings, including community behavioral health settings or in private practice.

Studies to Advance Autism Research and Treatment

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Definition

A federally funded network of studies was mandated by the Children's Health Act (2000) that

was to include at least five centers of excellence in autism research. In response to this mandate, five NIH institutes (NIMH, NICHD, NINDS, NIDCD, and NIEHS) came together to develop a network program. This program of work was concerned with aspects of diagnosis, early detection, prevention, and treatment as well as the etiology of autism. This program was the successor to the original Collaborative Program of Excellence in Autism which had been funded by NICHD and NIDCD.

Following a competitive process, eight centers around the country were funded using the mechanism. These included:

- Boston University (Helen Tager-Flusberg, Ph.D., principal investigator)
- Kennedy Krieger Institute (Rebecca Landa, Ph.D., principal investigator)
- Mt. Sinai Medical School (Eric Hollander, M.D., principal investigator)
- University of California, Los Angeles (Marian Sigman, Ph.D., principal investigator)
- University of North Carolina at Chapel Hill (Joe Piven, M.D., principal investigator)
- University of Rochester (Patricia Rodier, Ph.D., principal investigator)
- University of Washington (Geri Dawson, Ph.D., principal investigator)
- Yale University (Fred Volkmar, M.D., principal investigator)

In addition to studies conducted at each site, the network also worked on a series of collaborative projects.

Definition

Prevalence of autism spectrum disorders (ASDs) consists in the number of people identified with an ASD in a defined population divided by the total number of people in the population at a given time. Prevalence is usually expressed as x people per 1,000 with an ASD in the area studied. Determining the prevalence of the ASDs depends on the identification of people with an ASD in a defined population. Prevalence studies must first

define the “case definition” by describing who will be counted as having an ASD and by what standards. Some prevalence studies have sought to identify specific subtypes such as autistic disorder or Asperger’s disorder, while others have focused on the whole spectrum. The way ASDs are defined and the methods used to identify the conditions can have an impact on prevalence estimates. One major difference among prevalence studies is whether the focus is on counting individuals who have already been diagnosed or classified as having an ASD or on identifying individuals who have the diagnostic profile of certain ASDs who may or may not have already been diagnosed. There are several methods used to identify people with an ASD in the population. These include counting the number of people already identified with an ASD either through service systems or registries or by conducting surveys asking if a person has an ASD diagnosis. Other methods include trying to not only count people already diagnosed with an ASD but also identify people who meet the diagnostic criteria but have not yet been diagnosed with an ASD. These efforts attempt to screen records or people in the population to find already-known and currently unknown cases of ASDs. All prevalence studies require that you know the base population of people from whom you are trying to identify the individuals with an ASD.

The number of people receiving services for identified ASDs has increased substantially since the early 1990s. This has been documented in the US Department of Education counts of children identified with autism for special education purposes and among statewide service systems for people with developmental disabilities (Centers for Disease Control and Prevention [CDC] 2009, 2012; Newschaffer et al. 2005). However, the number of individuals receiving services for ASDs is likely to be an underestimate of all people with ASDs in the population. In fact, methods that rely on service systems, registries, and surveys of people already diagnosed under-ascertain people without a diagnosis. Epidemiologic studies which systematically screen the population to also identify individuals who meet the case definition but who were not previously classified as having an

ASD generally result in higher and more complete prevalence estimates. Screening can focus on groups at risk who have been identified for some type of developmental concern in order to maximize resources and minimize false positives. A multisite study using this method found that 21% of the children identified with ASDs did not have a previous classification documented in their records (CDC 2012). Screening can try to identify ASDs among the general population. These studies generally report the highest prevalence estimates of ASDs (Baron-Cohen et al. 2009; Kim et al. 2011), but also must address challenges of low response rates and the possibility of over identification of people who have autism-like traits who may not have the constellation of functional impairments necessary to identify autism as a developmental disability. Overall, studies using a variety of methods have recently estimated about 1% of children with ASDs; however, estimates vary based on the methods used. The fact that there have been changes in the conceptualization of autism coupled with gains in community awareness over the past two decades poses challenges in knowing exactly how many people have really had autism or a related condition throughout history. However, it is clear that more people are identified with an ASD today than ever before, resulting in major needs for supports and services across the life span.

Stuttering

Elizabeth Schoen Simmons
Department of Psychological Sciences,
University of Connecticut, Storrs, CT, USA

Synonyms

Disfluency

Definition

Stuttering is a speech disorder in which the flow of speech is disrupted by involuntary repetitions (e.g., a-a-a-apple) and prolongations of sounds (e.g., Ssssit down), syllables (e.g., pat-pat-patriotic), words, or phrases; involuntary fillers (e.g., “um,” “like”); or silent pauses in which the speaker is unable to produce sounds. Stuttering can be variable in certain situations depending on the anxiety level connected with that activity. Although the precise etiology is not known, both genetics and neurophysiology are thought to contribute. Speech therapy is the primary treatment. It

generally aims to increase fluency or modify the stuttering behaviors.

Stuttering typically begins during childhood – approximately 2.5% of children under the age of 5 stutter. It can last throughout the lifetime, although approximately 75% of individuals who begin stuttering during the preschool years recover by their early teens. The overall prevalence of stuttering is approximately 1% of the population. If severe and persistent, it can significantly impact academic, social, and vocational outcomes. Differential diagnosis is required to distinguish between word retrieval and language formulation difficulties which can also cause disfluent speech.

Sub-Saharan Africa and Autism

Joseph A. Cornett

Psychology and Global Health, Yale College,
Yale University, New Haven, CT, USA

Historical Background

Sub-Saharan Africa is the sum of 46 countries located fully or partially south of the Sahara Desert. As a region, Sub-Saharan Africa (SSA) is as heterogeneous as its vast geographical scale would suggest: within it are more than 24 million km², more than a billion people (World Bank 2015), and more than 2000 languages (Epstein and Kole 1998). Because of this intraregion diversity, Pan-African organizations such as the African Union often divide SSA into several local subregions. Nevertheless, SSA is seen as a distinct geographical and political region by many global organizations, including the World Bank and the United Nations (UN) (United Nations 2014; World Bank 2014). Most of the 46 countries in SSA are low income – 41% of all people in SSA live on less than 1.25 USD per day (United Nations 2015). Although almost 90% of the world's children and adolescents live in low- and middle-income countries (LMICs), only about 10% of randomized controlled mental health trials for this population are conducted there (Kieling et al. 2011). Clinical interventions, service developments, research, and policy work for children and adolescents in SSA have focused almost exclusively on communicable diseases such as malaria, tuberculosis (TB), and human immunodeficiency virus (HIV), and on reducing infant mortality (United Nations 2015); there has been comparatively little focus on noncommunicable

diseases and neurodevelopmental disorders such as autism spectrum disorder (ASD) (Franz et al. 2017). Over the past few decades, successful decreases in mortality among children under 5 years of age in SSA (Garenne and Gakusi 2006; Mathers and Loncar 2006; Murray et al. 2007; Rajatnaram et al. 2010; United Nations 2015) have been followed by international calls to increase focus on the needs of children with developmental delays or disabilities, including ASD (Engle et al. 2007; Scherzer et al. 2012).

Autism research and resources within SSA are disproportionately located in South Africa and Nigeria (Abubakar et al. 2016b; Ruparelia et al. 2016), two of the most populous nations in the region and two of the richest by GDP per capita (World Bank 2013). A recent review found that more than half of high-quality peer-reviewed research on autism in SSA was conducted in South Africa (51%) and another 23% in Nigeria (Abubakar et al. 2016b). South Africa also differs from much of the rest of SSA in important ways; for example, it is the only nation in the region with less than 40% of its population under 15 years of age and one of only two regional nations with a fertility rate below the world average (Central Intelligence Agency 2016). For more information about autism research, treatment, and resources in South Africa, refer to its national entry referenced in the “See Also” section of this entry. Research from South Africa will not be discussed in this entry to maintain a complementary focus on the rest of SSA.

The history of autism in Sub-Saharan Africa is a relatively short one. Early thought hypothesized that autism was a culturally bound disorder and essentially nonexistent in SSA. It was not until 1978 that a psychiatrist, Victor Lotter, brought international attention to autism in the region, having identified children with autism in Ghana, Kenya, Nigeria, South Africa, Zambia, and Zimbabwe (Lotter 1978). Thirty of the children screened by Lotter had “autistic-like” behaviors, and nine met DSM criteria for the disorder. Lotter observed that the African diagnosed group was broadly comparable to a group of children diagnosed with autism in Britain in terms of the group's breadth of verbal and intellectual abilities, sex

ratio, breadth of socioeconomic status, and occurrence of epilepsy (Lotter 1978). Lotter also observed that repetitive movements and object-centered ritualistic behaviors were uncommon in the African sample, though contradictory findings have since been presented by several studies (Bakare and Ikegwuonu 2008; Bello-Mojeeed et al. 2011; Dhadphale et al. 1982; Holford 1994; Izuwah et al. 2016; Lagunju et al. 2014; Springer et al. 2013; Szabo and Aber 1992; Wessels and Pompe van Meerdervoort 1979). International dialogue continued regarding the “open question” of the universality of ASD (Sanua 1984), but reviews of case reports around the world have since concluded that ASD has substantial worldwide prevalence (Fombonne 2003). Increasing interest in ASD in Africa is currently demonstrated in, among other indicators, the growing number of regional scientific studies on the topic (Ametepee and Chitiyo 2009; Bakare and Munir 2011a). A recent review concluded that 83% of peer-reviewed research on autism in SSA (including South Africa) had been conducted after 2006, indicating a dramatically increased interest over the previous decade (Abubakar et al. 2016b).

The global prevalence of ASD is now estimated at 1–2% (CDC 2014; Elsabbagh et al. 2012; Kim et al. 2011). Around 50% of the African population is under 18 years of age, and given trends in birth rates around the world, the United Nations predicts that 40% of the world’s children will live in Africa by 2050 (UNICEF 2014). Although no population-based studies of ASD have yet been performed in SSA, due in part to barriers to accessing “gold standard” diagnostic tools in research, it has been suggested that there is little reason to believe regional rates of ASD will be lower than elsewhere (Abubakar et al. 2016b; Durkin et al. 2015; Franz et al. 2017). It has also been suggested that rates of ASD may be higher in SSA, following a pattern of greater reported prevalence of intellectual disabilities in South Africa and LMICs compared to in high-income countries (Adnams 2010; de Vries et al. 2013; World Health Organization 2011). The need for a global perspective on ASDs was publicly affirmed by the World Health Organization (WHO) in 2008 when its General Assembly

adopted a resolution designating the second day of April each year as “World Autism Awareness Day.” In 2013, the WHO Executive Board adopted a resolution entitled “Comprehensive and coordinated efforts for the management of autism spectrum disorders (ASDs)” (World Health Organization 2014). The resolution was supported by more than 60 member countries and calls upon Member States – including 40 countries in SSA – to address the needs of people with ASD worldwide (World Health Organization 2013).

Legal Issues: Mandates for Service

There are currently no legal mandates for ASD-specific services in any country in SSA. Political will to enact such legislation is limited by the lack of empirical data regarding the prevalence of autism in countries in SSA (Abubakar et al. 2016b; Ametepee and Chitiyo 2009; Bakare and Munir 2011a; Franz et al. 2017). Forty countries in SSA are members of the WHO and, as such, adopted the 2013 resolution on autism spectrum disorders (World Health Organization 2013), which urges member states to expand capacity for services, develop and implement policies, promote research and awareness, and focus on community-based treatment. The resolution focuses on an implementation period from 2013 to 2020. Yet while the WHO has firmly acknowledged ASD as a public health concern (World Health Organization 2013, 2014), no countries in SSA currently have effective policies or “good practice” guidelines in place for assessment, treatment, education, and adult support of persons with ASD.

Overview of Current Treatments and Centers

There are very few specialist resources in SSA for individuals with ASD and related neurodevelopmental disorders (de Vries 2016). In 2015, there were only 50 specialist child and adolescents psychiatrists in the entire continent and a much

smaller number of developmental pediatricians (de Vries et al. 2013). Additionally, it has been noted that published cases in Africa tend to be of children from higher socioeconomic backgrounds (Ametepee and Chitiyo 2009). The most likely explanation for this is that wealthier individuals live in closer proximity to medical centers in major cities and are therefore more likely to be able to access services. This observation that socioeconomic status is a correlate for access to services is analogous to similar observations in the USA (Durkin et al. 2010). Nonverbal rates for children with autism in SSA have been reported as high as 71%, compared to only 25% in the USA (Bakare and Munir 2011b), and an autism diagnosis in SSA often co-occurs with epilepsy or intellectual disability. This suggests that reported cases are skewed toward the more severe and recognizable cases with comorbidities, indicating a severely underestimated prevalence of more moderate cases (Bakare and Munir 2011b).

Even when a diagnosis is given, it is difficult to find appropriate services. There are far too few mental healthcare facilities, personnel trained to work with autistic children, and specialist educational and behavioral interventions compared to the estimated prevalence of autism in SSA (Bakare and Munir 2011b). Many Africans have spiritual beliefs about psychiatric disorders, evident in the perceived etiology of autism among both caregivers and the general public. In a survey of Nigerian pediatric and psychiatric nurses, 40% cited preternatural causes of autism such as ancestral spirits or actions of the devil (Bakare et al. 2008). Supernatural explanations of autism can influence treatment-seeking behaviors of caregivers by encouraging use of spiritualists and traditional healers before other professionals.

Treatment in SSA is limited by a lack of validated measures for diagnosing and treating ASD in an African context. Additionally, very little systematic data about ASD in SSA is available, due in part to the absence of centralized bodies tasked with monitoring available services. Designing treatments in this context thus presents a methodologically difficult task. Recent reviews of published literature have emphasized the need to invest more in identifying potential screening

and diagnostic tools for the SSA context, as access to such tools can contribute to early identification of children with ASD (Abubakar et al. 2016b; Ametepee and Chitiyo 2009; Bakare and Munir 2011a; Franz et al. 2017). Preliminary studies have indicated some tools with moderate validity. These include a study in Uganda that adapted and extended the Ten-Question Questionnaire (TQQ) into a 23-item questionnaire, modestly successful in identifying subgroups of children at high risk of being diagnosed with ASD (Kakooza-Mwesige et al. 2014), as well as a study in Tanzania that evaluated a culturally adapted Childhood Autism Rating Scale as a structured tool to diagnose ASD locally – after ensuring that the play interactions, materials used, and social routines used to probe the child's behavior were familiar to the child – concluding that the tool had excellent discriminative validity and acceptable levels of sensitivity and specificity (Harrison et al. 2014). Because of the remarkable cultural and linguistic diversity within SSA (Epstein and Kole 1998), tools that are validated in one region must be systematically validated in each new region. The few intervention studies that exist have limited sample sizes, are largely cross-sectional, and lack evaluation of long-term impact (Abubakar et al. 2016b). Altogether, the precedence of interventions for children with ASD in SSA is not yet adequate to plan large-scale effective intervention strategies in SSA.

As there is no legal mandate for support of families with ASD, the bulk of support and services for families of children with ASD are provided by nongovernmental organizations (NGOs); existing NGOs also raise awareness about autism in Africa (Newton and Chugani 2013). These organizations are a significant part of the ASD treatment landscape in SSA. It should also be noted that the majority of African countries, including South Africa, have few specialist educational facilities for school-aged children with ASD (de Vries 2016). Moreover, in most parts of SSA, there appear to be no residential treatment facilities specifically for adults with autism, either with or without intellectual disability. For a list of some of the organizations engaged in providing resources and services and raising

awareness as of publication, refer to the “[Resources and Readings](#)” section appended to the entry.

Overview of Research Directions

Research output from SSA regarding autism is scarce. This contributes to the broader “10–90% divide” in research: while almost 90% of the world’s children and adolescents live in low- and middle-income countries (LMICs), only about 10% of randomized controlled mental health trials for this population are conducted there (Kieling et al. 2011). Global reviews of peer-reviewed publications on autism have come to the same conclusion. One found only 120 data-driven publications on autism from SSA, even before screening them for methodological rigor, compared to 511,560 publications from North America and 57,577 from Europe (Franz et al. 2017). More than half of published autism research in SSA has been carried out in South Africa alone, and of the research conducted outside South Africa, nearly half of that is from Nigeria (Abubakar et al. 2016b). Research centers in SSA specializing in autism are scarce. For specific research center information sorted by country, refer to the “[Resources and Readings](#)” section appended to the entry.

This lack of literature from SSA may be due to several factors. Firstly, there is a lack of regional expertise in ASD. In 2013, there were only 50 specialist child and adolescent psychiatrists across the entire continent of Africa and a much smaller number of developmental pediatricians (de Vries et al. 2013). Secondly, there is not sufficient investment in autism research to enable widespread methodological rigor (Ruparel et al. 2016). This includes a lack of investment in producing standardized tools that have been validated in the African context, a significant barrier to data-driven research toward screening and diagnosis of autism (Abubakar et al. 2016b). For more information on the preliminary validation of tools for diagnosis and screening, refer to the “[Overview of Current Treatments and Centers](#)” section of the entry. Broader involvement from

multidisciplinary clinical and academic colleagues across all academic medical centers, particularly in the development of validated tools for screening and diagnosis, remains an important need.

Of the limited research in SSA, most focuses on the psychosocial aspects of assisting someone with ASD. This focus on health workers and caregivers for children already diagnosed with ASD may be due to the difficulty of additional diagnosis and the minimal resources available for such a task (Abubakar et al. 2016b; Franz et al. 2017). Additionally, this focus on the psychosocial aspects of ASD may reflect an increasing appreciation for the significant burden on quality of life in African communities due to ASD and a growing interest in managing and averting this burden (Abubakar et al. 2016a). These psychosocial studies largely focus on three themes: (a) awareness levels among various subpopulations, (b) quality of services provided to children with ASD and challenges for caregivers, and (c) sociocultural aspects regarding ASD, including cultural explanatory models for the etiology of ASD (Abubakar et al. 2016b). Most of these studies were carried out in Nigeria by Bakare and colleagues (Abubakar et al. 2016b; Bakare et al. 2008, 2009a, b, c, 2011, 2015). A study in Tanzania developed an intervention to raise awareness of ASD and help caregivers learn some basic behavioral intervention strategies, including teaching of basic social skills (e.g., eye contact and imitating) and self-help skills (e.g., feeding) (Harrison et al. 2014, 2016). This intervention was found to be feasible to implement, and almost all participating caregivers found it to be useful. Findings regarding cultural and social policies are described in greater detail in the “[Cultural Factors and Controversies](#)” section of the entry.

A few studies have attempted to estimate the burden of ASD in SSA. Prevalence of ASD in this region, as in most low- and middle-income countries (LMICs), is still unclear (Bakare and Munir 2011a; Newton and Chugani 2013; World Health Organization 2013). A recent review found only a single population-level study aimed at documenting the prevalence of ASD in a country in SSA (Kakooza-Mwesige et al. 2014) and not a

single case-control study aimed at examining a comprehensive set of potential risk factors (Abubakar et al. 2016a). Most of these studies have used convenience sampling, sourced largely from hospitals and specialist units for children with special needs, which skews the prevalence and comorbidities of ASD in the sample population. For example, a study of 2320 patients at a pediatric neurological clinic in Nigeria diagnosed 54 patients with ASD, at an estimated prevalence of 2.3%, and found neurological comorbidities in 75.5% of those diagnosed (Lagunju et al. 2014). A single community-based study in Uganda surveyed 1169 children aged 2–9 in the Kampala District – half-urban, half-rural – wherein eight children had a positive diagnosis of ASD, resulting in an unadjusted prevalence for ASD of 6.8/1000, which the authors suggested was likely underrepresentative (Kakooza-Mwesige et al. 2014). All studies included in recent reviews have found a higher prevalence among boys compared to girls, in line with sex ratios in other global regions (Abubakar et al. 2016b; Ametepee and Chitiyo 2009; Bakare and Munir 2011a; Franz et al. 2017).

Overview of Training

Autism awareness, even among health professionals, is low in most parts of SSA. While a significant proportion of studies of ASD in SSA have investigated awareness of ASD among various subpopulations, most of these were carried out in a single country, Nigeria. An important step in gauging knowledge of ASD among health workers has been the development of the Knowledge about Child Autism among Health Workers (KCAHW) questionnaire, a validated and standardized tool for such evaluations in the Nigerian context. Bakare and colleagues developed this questionnaire and evaluated its psychometric properties using a sample of psychiatric nurses; they found that the measure had excellent internal consistency and adequate test-retest reliability (Bakare et al. 2008). Using this questionnaire to evaluate a sample of 134 health workers in Nigeria, Bakare and colleagues noted that a significant

percentage still held negative or false beliefs about the etiology, treatability, and preventability of ASD (Bakare et al. 2009a). In a related study, the same sample of health workers exhibited their most salient knowledge gaps in symptoms of obsessive behavior and impairments in social interaction (Bakare et al. 2009b). While general health workers exhibited poor knowledge of ASD, Bakare and colleagues also found that knowledge of ASD was quite good among final-year medical students, though important knowledge gaps were still noted in this population (Bakare et al. 2015). Eseigbe and collaborators (2015) used the KCAHW questionnaire to evaluate knowledge of ASD among a sample of 167 Nigerian medical doctors. They observed that pediatricians and psychiatrists had the best relative knowledge of ASD, that the most significant knowledge gap was regarding the onset of ASD and its comorbidities, and that the least significant gap was regarding communication impairments (Eseigbe et al. 2015). Igwe and collaborators (2011) found that even among Nigerian pediatric and psychiatric nurses, there was a significant deficit in ASD knowledge, particularly regarding the initial onset of ASD (Igwe et al. 2011).

Documented interventions, in peer-reviewed literature, intended to increase awareness of ASD are rare. In Tanzania, one such study reported a successful intervention intended to improve caregiver skills, focusing on basic behavioral strategies such as teaching basic social skills (e.g., making eye contact and imitating) and self-help skills (e.g., feeding) (Harrison et al. 2014, 2016). Education of healthcare workers is crucial for early diagnosis of ASD, so that early intervention programs can be delivered when they are most effective. For specific organizational resources, refer to the “[Resources and Readings](#)” section appended to the entry.

Cultural Factors and Controversies

There is a significant lack of awareness regarding ASD, particularly in rural areas where specialist care is effectively nonexistent (Ruparel et al.

2016). This lack of awareness, in combination with a lack of evidence-based treatments, has contributed to misconceptions about the nature of the disorder and the proper means for diagnosing and managing it. In a survey of Nigerian pediatric and psychiatric nurses, 40% cited preternatural causes of autism such as ancestral spirits or actions of the devil (Bakare et al. 2008). Yet while supernatural powers are a common attributed cause of autism, they are by no means the only common attribution. Attributed etiologies in SSA populations regarding mental health and developmental disorders, including autism, often span a wide range of beliefs, even within an individual. In a survey of caregivers in Ethiopia, explanations for the condition of a child with ASD included a mix of biomedical explanations (e.g., head injuries, given by 30.4% of participants), birth complications (25.5%), and supernatural explanations (e.g., spirit possession (40.2%) and sinful acts (27.5%)) (Tilahun et al. 2016). Gona et al. (2015) conducted in-depth interviews and focus groups with parents and professionals in Kenya – spanning communities in urban and rural settings with high and low literacy levels, Christian and Muslim faiths, and a range of educational levels. In line with the aforementioned survey of caregivers in Ethiopia by Tilahun et al. (2016), all participants in the Kenyan study by Gona et al. (2015) described preternatural causes (evil spirits, witchcraft, and curses) as well as medical causes (infections, drugs, birth complications, and genetics) as contributors to the etiology of ASD (Gona et al. 2015). All participants also indicated use of a range of treatment options, regardless of socioeconomic status or cultural background, that included visits to hospitals for “modern” healthcare treatments as well as consultations with traditional and spiritual healers (Gona et al. 2015). While these studies should not be hastily generalized to the rest of SSA, current literature would suggest that pluralistic perceived etiologies and preferred treatments of ASD in SSA cross socioeconomic, cultural, and religious divides. Accordingly, researchers strongly suggest that healthcare professionals should take care to explore the cultural beliefs of African families and account for the pluralism contained within,

thereby ensuring sensitivity to cultural nuances in beliefs regarding a child’s condition (Gona et al. 2015; Tilahun et al. 2016).

The challenges facing caregivers of children with ASD and caregivers’ common coping strategies are also broad and pluralistic. Common challenges include stigma, lack of appropriate health services, financial burdens, and heavy practical and emotional burdens (Gona et al. 2016). Coping strategies among a sample of Kenyan parents of children with ASD included problem-focused aspects (e.g., diet management and respite care) as well as emotional-focused aspects (e.g., belief in supernatural powers, prayers, and spiritual healing) (Gona et al. 2016). Among caregivers in Ethiopia, coping mechanisms for dealing with stigma of ASD were most commonly support from friends (reported by 76.5% of participants) and prayer (reported by 57.8% of participants) (Tilahun et al. 2016).

Access to specialist education facilities for school-aged children with ASD is rare (de Vries 2016). A survey of caregivers in Ethiopia reported that educational provision was their single greatest unmet need (reported by 74.5% of participants), even greater than treatment by a health professional (reported by 47.1% of participants). A study in Zimbabwe examined common barriers to including children with ASD in mainstream classrooms; these barriers included social rejection, communication impairments, and behavioral challenges of children with ASD (Majoko 2016). Collaborating with stakeholders to promulgate training for regular teachers and to enhance social support services may be effective strategies for encouraging inclusion of children with ASD in mainstream educational settings; these strategies may be more feasible than providing widespread specialist educational facilities (Majoko 2016).

Documented interventions to improve caregiver skills are rare in peer-reviewed literature (Abubakar et al. 2016b; Ametepee and Chitiyo 2009; Bakare and Munir 2011a; Franz et al. 2017). One such intervention was successfully implemented in Tanzania with a focus on improving basic behavioral strategies for caregivers such as teaching basic social skills (e.g., making eye contact and imitating) and self-help skills (e.g., feeding) (Harrison et al.

2014, 2016). In designing an intervention, cultural validation is essential to achieving the desired impact, as local cultural behaviors may substantially impact the manifestation and visibility of ASD. For example, a study in South Africa noted that direct eye contact with elders is discouraged and potentially seen as disrespectful among the general population; in this context, relying on avoidance of eye contact as an indicator for ASD would be less effective (Grinker et al. 2012). Education of the public is crucial for early diagnosis of ASD and minimizing stigma. NGOs are making significant contributions to autism awareness in SSA – refer to the “[Resources and Readings](#)” section appended to the entry for a partial list of specific organizations that are contributing to minimizing the impact of stigma and maximizing the availability of resources. Much of the existing research literature focuses on the psychosocial aspects of ASD for the child and for their families. This may be a favorable indicator of a greater appreciation for the significant burden on quality of life due to ASD in African communities as well as a growing interest in developing best practices for managing and averting this burden (Abubakar et al. 2016b).

Introduction

Autism spectrum disorder (ASD) is a heterogeneous condition defined by social deficits, restrictive interests, and repetitive behaviors. Individuals with ASD demonstrate highly variable levels of

intellectual abilities, verbal skills, and adaptive functioning (American Psychiatric Association 2013). Psychiatric and medical comorbidities are frequently co-occurring in ASD, including anxiety, depression, attention deficit hyperactivity disorder (ADHD), obsessive compulsive disorder (OCD), seizure disorder, sleep disorder, and a broad range of various somatic disorders (Bauman 2010; Joshi et al. 2010; Mattila et al. 2010; Muskens et al. 2017; Simonoff et al. 2008). However, little is known about the rates of substance use problems or substance use disorder (SUD) in this group. A recent literature review found that clinical assessment of substance use among individuals with ASD is infrequent, and the overall scientific evidence and understanding of potential relationships between ASD and SUD is very limited (Palmquist et al. 2014).

Current Knowledge

Increasing numbers of individuals with ASD demonstrate high functioning and independent living status (Howlin 2005; Howlin et al. 2004). Additionally, ASD individuals are frequently prescribed medications that may have addictive properties or have misuse or abuse potential (Siegel and Beaulieu 2011; Williamson and Martin 2010). Consequently, the true scope of substance use problems among individuals with ASD can potentially be larger than suggested by researches conducted to date. While an overall prevalence of substance use disorders in individuals with neurodevelopmental disorders is not known, a recent systematic review by Arnevik and Helverschou (2016) reported a range of SUD prevalence rates between 0.7% and 36% among individuals with ASD. The largest study included in the review based on data from a national register in Denmark (Abdallah et al. 2011) included 414 individuals with ASD and reported that only three (0.7%) individuals in the cohort were diagnosed with alcohol related disorders (ARD). In contrast, one of the smallest sample studies included in the review by Mandell and colleagues reported a prevalence of 36% in a sample of 14 psychiatrically hospitalized

individuals with ASD. Most published studies report a lower prevalence of SUD in individuals with ASD than in individuals without ASD. However, small sample sizes and the pronounced selection biases in many of the published reports undermine generalizability or reliability of the reported findings (Arnevik and Helverschou 2016).

A small body of research explored the causes and consequences for substance use among individuals with ASD. It has been reported that while the use of substances can be perceived as helpful by ASD individuals by offering a temporary relieve of anxiety, mood, or other adverse symptoms, it often leads to overall long-term negative outcomes. For example, using substances to overcome social difficulties could have somewhat positive short-term effects, while having a long-term adverse effect on cognitive functioning (Kronenberg et al. 2014).

To summarize, little is known about substance use among individuals with ASD, the rate of co-occurrence is uncertain, and there is a significant lack of studies that address and evaluate interventions for individuals with ASD and substance use disorder. ASD is a relatively rare condition affecting approximately 1.7% of the general population (Baio et al. 2018). Consequently, the overall low ASD prevalence rate poses a significant challenge for research studies aimed to evaluate the rates of co-occurrence of ASD and SUD.

Future Directions

Further epidemiological research is needed to obtain better estimates of prevalence rate of co-occurring ASD and SUD and to assess potential implications for clinical care. As highlighted in the systematic review by Arnevik and Helverschou (2016), research should also focus on SUD treatment for individuals with ASD which is likely to require comprehensive approaches and might be more challenging than treatment for individuals with SUD alone. Research aimed to uncover specific treatment, social support, and other adjunctive services

needs of ASD individuals with SUD is also urgently needed. Furthermore, better understanding of potential causes for substance use or developing a SUD in individuals with ASD to be able to investigate why the rate of SUD is lower in ASD compared to other psychiatric disorders.

Substantia Grisea

► Gray Matter

Substantia Nigra

Danielle Bolling

Yale Child Study Center, New Haven, CT, USA

Definition

The substantia nigra consists of large dopamine-producing nerve cells in the midbrain, adjacent to the striatum. The structure is part of the basal

ganglia and consists of two subdivisions, the pars compacta and pars reticulata. This region has functional implications in reward, addiction, and movement, as damage to this area is associated with disorders such as Parkinson's disease.

Substantial Gainful Activity

Susan Luger
Susan Luger Associates, New York, NY, USA

Synonyms

Substantial gainful employment

Definition

Substantial gainful activity is a term used to describe a level of work activity and earnings. It is used by the social security administration to determine if a person is eligible for social security benefits. It refers to any work that is generally performed for pay or profit or intended for profit (even if there is none). It applies to full- or part-time work. It can also apply to self-employment.

Substantial gainful activity is not about whether you can perform your job. It is not about whether you can or cannot find work. It is about whether you can work at any employment activity that is generally available. It includes salaried positions, attending school, or a volunteer activity even if you receive no salary. An activity qualifies as substantial gainful activity based on the amount of income that is or could be earned. You are not eligible for disability benefits if you can perform any work that someone could have been paid for.

The Social Security Administration defines a dollar amount yearly that a person can earn and still maintain their eligibility for SSI or social security benefits. Those who earn (or could earn) over this minimum dollar amount are considered to be engaging in substantial gainful activity and, therefore, ineligible for Social Security benefits.

Subtest Scatter

Timothy Soto
Clinical Psychology, University of Massachusetts
Boston, Boston, MA, USA

Definition

Subtest scatter refers to a pattern or profile across subtests in which subtest scores on a standardized test vary a great deal. Most standardized subtest

scores have a mean, or average, score of 10. Children will often score within three points above or below the mean of 10 (i.e., scores between 7 and 13) (or above and below their own mean score across subtests, which may be higher or lower than 10). If significant scatter exists, meaning the difference between the highest and lowest subtest scores is greater than six points, this suggests that the test taker has areas of strength and weakness that need to be further explored. When interpreting standardized test results of an individual with an autism spectrum disorder, it is important for educators, the individual, and/or parents to understand the nature of the weak areas or areas of relative weakness, what skills need to be learned to strengthen those areas (e.g., utilizing strengths to develop skills in area of weakness), and what specific accommodations should be implemented to facilitate the remediation of the weak areas. Understanding areas of strength or relative strength can often inform remediation of weaknesses.

Historical Background

Researchers have been analyzing IQ subtests for more than 70 years (Zachary 1990). Early researchers hypothesized that subtest scatter would predict academic potential. Additionally, uneven subtest scores were assumed to be indicative of psychopathology. Specifically, psychologists speculated that subtest scatter of an individual's scaled scores across subtests on an intelligence battery might be a sign of neurological dysfunction (Drebing et al. 1994), learning disability (McLean et al. 1990), or emotional disability (Drummond 2000). While some studies found subtest scatter to be associated with clinical groups, differences tended to disappear when adequate comparison samples were used (Zimmerman and Woo-Sam 1985). Furthermore, subtest scatter was also found to be unrelated to academic achievement (Hale and Saxe 1983; Kline et al. 1992).

A source of data that has greatly contributed to the understanding of IQ subtest analysis is the Dunedin Multidisciplinary Health and

Development Study (DMHDS; Silva 1990). The DMHDS included a sample of more than 1000 New Zealand children assessed with a battery of psychological, sociological, and medical measures every 2 years from birth to adulthood. Its representative sample, comprehensive assessment battery, and longitudinal design make DMHDS IQ test results unique in the professional literature.

Using data from the DMHDS, Moffitt and Silva (1987) reported on the clinical significance and stability of Wechsler Intelligence Scale for Children-Revised (WISC-R; Wechsler 1974) VIQ and PIQ scatter. They concluded that perinatal, neurological, and health problems did not cause extreme VIQ-PIQ discrepancies and found that neither behavior problems nor motor problems were significantly related to VIQ-PIQ scores. Furthermore, VIQ-PIQ score discrepancies were unreliable across time. That is, the majority of children with extreme VIQ-PIQ score discrepancies did not maintain such a large difference when tested with the WISC-R 2 years later. Thus, they concluded that VIQ-PIQ scatter may not be stable and does not adequately predict psychological diagnoses. The combined results from 94 studies, including 9372 total participants, also demonstrated that subtest scatter and scatter between VIQ and PIQ failed to uniquely distinguish children with learning disabilities (Kavale and Forness 1984). For example, the average VIQ-PIQ difference for children with learning disabilities was only 3.5 points – a difference found in 79% of the normative sample.

Even though subtest scatter was not found to indicate psychopathology or predict academic achievement, psychologists continued to examine individual subtest patterns. Specifically, examining an individual's scaled subtest scores began to be used to identify specific cognitive strengths and weaknesses (Zeidner 2001). Following this logic, a high degree of subtest variability or specific patterns of subtest scores were presumed to substantially invalidate global intelligence indices (Groth-Marnat 1997) so that subtests, rather than IQ composites, became the focus of interpretation. Psychologists believed that such a multidimensional view of intelligence would provide greater insight into the nature of human ability

than summary intellectual indices (Zimmerman and Woo-Sam 1985), particularly when trying to describe an individual's pattern of cognitive performance. Based on these principles, intricate subtest profile interpretation systems have achieved wide popularity in psychological training and practice (Aiken 1996; Groth-Marnat 1997; Kaufman 1994; Sattler 2001). For example, approximately 74% of school psychology training programs place moderate to great emphasis on the use of subtest scores in their individual cognitive assessment courses, and almost all use texts that advocate subtest analysis (Alfonso et al. 2000). As would be expected from such training, school psychologists frequently analyze cognitive subtest profiles in their practice (Pfeiffer et al. 2000). Among their sample of clinicians, for example, Pfeiffer et al. found that almost 70% reported factor scores/profile analysis to be a useful feature of intelligence tests and 29% reported that they derived specific value from individual subtests. Matarazzo and Prifitera (1989) noted that while some supportive WAIS-R subtest scatter research had been published, lack of cross-validation and replication deems interpretation of subtest scatter useful for creating hypothesis about an individual, but the results are not conclusive in and of themselves.

Current Knowledge

Subtest scatter has continued to receive clinical attention despite previous literature reviews demonstrating that it was ineffective for distinguishing clinical from typically functioning groups. Recent research results are remarkably consistent with past reviews, in that results indicate that subtest scatter is an invalid diagnostic indicator and incapable of reliably predicting academic achievement. Several studies are particularly important because they demonstrated no relationship between subtest scatter and academic achievement in large, nationally representative samples of students without disabilities (Kahana et al. 2002; McDermott and Glutting 1997; McGrew and Knopik 1996; Watkins and Glutting 2000; Youngstrom et al. 1999). Based on their review

of IQ subtest scatter research, Kline et al. (1996) suggested that psychologists have pursued scatter analysis with little success and that it is time to move on; this suggestion was further supported by McGrew and Knopik (1996). Given the body of research to date, it seems as though there is no scientific support for the use of subtest scatter to inform diagnosis or prediction.

Future Directions

Although there is general agreement that diagnoses based on IQ subtest scatter should be avoided, the use of subtest profiles and subtest scatter for hypothesis generation is frequently recommended (Sattler 2001; Kaufman and Lichtenberger 1998, 2000; Kamphaus 2001; Groth-Marnat 1997). Specifically, the examiner must first generate hypotheses about an individual's assets and deficits. Next, the examiner must confirm or deny these hypotheses by exploring multiple sources of evidence. Finally, well-validated hypotheses must then be translated into meaningful, practical recommendations, concerning interventions, instructional strategies, and remediation activities (Groth-Marnat 1997).

Treatment recommendations resulting from the hypotheses generated from interpretation of subtest profiles and subtest scatter should follow three basic guidelines. First, subtest profiles must be strongly associated with performance in such socially important endeavors as academic achievement and psychosocial behavior. If subtest profiles are not substantially related to important social criteria, then hypotheses generated from subtest variation may not be useful. Second, hypotheses based on subtest scatter or subtest profiles should be consistently confirmed by multiple pieces of other information, including pursuing additional testing to corroborate observed areas of weakness. Finally, interventions that result from hypotheses based on subtest performance must exhibit treatment validity; that is, they must selectively assist in the improvement of cognitive, achievement, or behavioral weaknesses.

Subtest interpretation systems provide hundreds of hypotheses to consider when IQ subtest

patterns are obtained (Kaufman 1994; Sattler 2001). For example, some comparisons that have been highlighted include the following: low performance on the Picture Arrangement (PA) and Comprehension (CM) subtests suggests poor social adjustment, as seen in autism spectrum disorders; equal VIQ and PIQ scores may indicate an absence of emotional distress; a large difference in performance between digits forward and digits backward indicates anxiety; and low scores on Digit Span (DS), Arithmetic (AR), and Coding (CD) subtests identify anxiety, attentional deficits, or both (Banas 1993; Drummond 2000; Groth-Marnat 1997; Kellerman and Burry 1997).

The relationship between social adjustment and performance on PA and CM subtests has received considerable attention. Lipsitz et al. (1993) administered Wechsler scales and two measures of social adjustment to groups of high-risk and typical comparison children. PA scores showed no relation with either measure of social adjustment. Further, Campbell and McCord (1996) found that PA scores were not significantly better than FSIQ scores in predicting participants' ability to interpret the nonverbal behavior of others. These negative results for the PA subtest have been replicated with different samples, criterion tests, and IQ tests (Beebe et al. 2000; Campbell and McCord 1999). Consequently, making an inference regarding social adjustment/judgment based on PA scores is contraindicated by research.

Definition

Subtypes of autism can be defined as groups of persons with autism spectrum disorders (ASD) who are posited to be more similar to each other than to the larger group of individuals who fall under the broad diagnostic category of ASD. Identification of subtypes may facilitate efforts to understand etiology of ASD as well as differential response to treatment. These subtypes are most often defined by a particular behavior or set of behaviors, such as cognitive or language abilities. However, they may also be defined by other characteristics, such as patterns of development or physical features.

Historical Background

Autism spectrum disorders (ASDs) are characterized by impairments in communication and reciprocal social interaction and the presence of restricted and repetitive behaviors and interests. Although ASDs are defined based on this triad of impairments, the presentation of these symptoms varies widely from one individual to another. Behaviors are further impacted by variability in other factors, such as age, level of language, and cognitive ability. This heterogeneity makes it difficult for researchers seeking to elucidate causes or risk factors for ASD or develop and test the efficacy of interventions. Common sense would suggest that it is unlikely that the same etiological

factors would explain two vastly different phenotypes (e.g., a nonverbal child with profound intellectual disability and a verbally fluent child with a superior IQ). Similarly, it would not be expected that those two individuals would respond equally to the same type of intervention. However, at this point, there is relatively little data to answer these questions.

In an attempt to reduce the variability observed in ASDs, researchers have sought to identify groups of individuals within the autism spectrum with the hope that these “subtypes” may represent a more homogeneous group that has a greater likelihood of being etiologically distinct (Newschaffer et al. 2002) or responsive to a certain type of intervention (see Schreibman and Ingersoll 2011). A summary of some subtypes is provided below; however, it is important to recognize that subtypes in ASD are still being actively researched and definitions are continually being modified to reflect the most recent findings. The question still remains as to whether these subtypes will lead to increased understanding of the etiology or prognosis for some individuals with ASD and whether these will ever have clinical utility, allowing clinicians to better explain the causes of a child’s difficulties or choose the most appropriate treatment for that child.

Categorical Diagnoses

The earliest descriptions of autism described by Kanner in 1944 noted the variability in symptom manifestation and severity. Yet, it was not until 1980, with the American Psychiatric Association’s publication of DSM-III, that such variation was noted in the diagnostic criteria with the category of “Atypical Pervasive Developmental Disorder” included to capture children who did not meet full criteria for infantile autism. This category was renamed “Pervasive Developmental Disorder-not otherwise specified” in DSM-III-R (1987). In addition to Autistic Disorder and PDD-NOS, other categories of ASD (i.e., Pervasive Developmental Disorders) were added in DSM-IV, including Asperger’s disorder, Child Disintegrative Disorder, and Rett’s disorder.

These diagnostic categories were among the early attempts to capture the behavioral

heterogeneity observed in ASD by distinguishing subtypes of persons showing different kinds and levels of symptoms and/or patterns of onset. However, over time, it has been increasingly recognized that, even within these diagnostic subtypes, there remains a great deal of variability in symptom presentation and course. Furthermore, although ASDs are reliably distinguished from typical development and other non-ASD developmental disabilities, differentiations within the autism spectrum (i.e., Autistic Disorder, Asperger’s disorder, and PDD-NOS) have been generally inconsistent (Lord et al. 2012). Efforts to demonstrate measureable differences between groups have not been particularly successful. For example, studies comparing the cognitive profiles of individuals with Asperger’s to those deemed as having “high-functioning autism” (i.e., a diagnosis of Autistic Disorder and IQ in the average to above average range) have provided mixed results. In general, these studies have not supported the categorical distinction made between these two groups (see Joseph 2011).

Given that these diagnostic categories have not yielded meaningful subgroups, the Neurodevelopmental Disorders Work Group has proposed that DSM5 includes a single diagnostic category of ASD with clinical specifiers (e.g., to indicate severity and verbal ability) and associated features (e.g., known genetic etiologies, such as fragile X, intellectual disability, etc.). Previously differentiated categories of Autistic Disorder, Asperger’s, and PDD-NOS will no longer be used in clinical practice.

Cognitive Subtypes

Cognitive abilities observed in ASD range from severely intellectually disabled to performance in the superior range on tests of intellectual functioning. In contrast to early studies suggesting that 75% of children with ASD have intellectual disability (ID), recent estimates are closer to 25–50% (Charman et al. 2011; Joseph 2011). In an early study comparing children with ASD and ID to those who did not have cognitive impairments (i.e., IQs <70 and >70), Bartak and Rutter (1976) reported group differences in ASD-related symptoms as well as educational and employment

outcomes. These authors hypothesized that the origin of autism may differ for children with and without intellectual disability and highlighted the importance of considering intellectual functioning in studies assessing etiological factors in autism. Although studies have found differences in genetic transmission of ASD for individuals with IQs over 70 (see Joseph 2011), results must be interpreted cautiously, as is possible that the identified loci are more generally related to IQ than ASD (Liu et al. 2008). It is also important to note that, while some studies have reported familial clustering of IQ in twin and sibling studies, conclusions are often based upon moderately sized correlations with wide confidence intervals (e.g., Szatmari et al. 2008), and, in many multiplex families, there are vast discrepancies in children's cognitive abilities (see LeCouteur et al. 1996).

Aside from general level of functioning, investigators have also questioned whether particular cognitive profiles, such as a large discrepancy between verbal and performance IQ, might reflect etiological differences in ASD (Joseph 2011). Early studies emphasized strengths in nonverbal abilities compared to language skills in children with ASD (Lockyer and Rutter 1970). Since then, researchers have sought to understand how the early development and severity of symptoms of children with this profile may differ from children with ASD who do not demonstrate this discrepancy. There is some evidence that discrepant cognitive profiles may be associated with enlarged head circumference and increased gray matter volume (see Joseph 2011). While there is no doubt that consideration of large differences in IQ is important to long-term outcomes (e.g., comparing individuals with and without ID; Howlin et al. 2004), the existence of categorical cognitive subtypes is not yet clear.

Language Subtypes

A substantial body of research has focused on whether age of language acquisition should be used to differentiate between Autistic Disorder and Asperger's and whether children with or without a language delay may represent etiologically different subtypes. These subtypes have generated a great deal of interest, given that increased

associations with various chromosomal abnormalities have been found in quantitative trait loci (QTL) analyses for age of language acquisition and linkage analyses using samples stratified by whether or not the proband had delayed language (see Cantor 2011; Lamb 2011 for reviews). However, not all studies using this method have yielded positive results. These inconsistencies could be related to differences across samples. Group comparisons of children with and without language delays show differences in age, cognitive level, and overall severity of symptoms, suggesting that if samples differ on these characteristics, associations with biological mechanisms may not be replicated across studies (Hus et al. 2007). There is also evidence that error in retrospective recall of language milestones, upon which most studies rely, could result in children being inaccurately grouped as language delayed, particularly for children with cognitive delay (Hus et al. 2011). Bennett et al. (2008) have suggested that current language level may be a more meaningful marker than history. While these considerations may help to explain inconsistencies across studies, they also suggest that age of language acquisition could be an index for general level of functioning, rather than a more specific subtype. While children with cognitive impairment may be a group of interest in and of themselves, highlighting associations between biological mechanisms and language subtypes can be misleading if these subtypes actually indicate more global impairments.

A range of current language abilities, apart from different histories, are observed in conjunction with ASD. Tager-Flusberg et al. (2011) briefly highlight three language subtypes within ASD – (1) individuals who are verbally fluent and do not have difficulties with structural aspects of language (e.g., vocabulary, syntax, phonology); (2) individuals who acquire varying degrees of functional language, though acquisition may be delayed, development may be slowed, and they may have ongoing difficulties in different areas of language; and (3) individuals who remain nonverbal (i.e., do not develop the ability to speak).

Many researchers have been particularly interested in the second group, i.e., those who acquire

functional speech but exhibit difficulties that overlap with those associated with specific language impairment (SLI). Although definitions of SLI generally require that language difficulties are independent of ASD, some researchers have questioned whether this criterion is appropriate or if some children should be considered as having a comorbid diagnosis of ASD and SLI (see Tomblin et al. 2011 for review). Similar patterns of neuroanatomical asymmetry have been reported in children with SLI and children with ASD and language impairments. Moreover, genetic variation within CNTNAP2 has been associated with both ASD and SLI; most interestingly, the same genetic polymorphism on this gene was related to parent-reported age of language acquisition in children with ASD and phonological short-term memory in children with SLI (see Tomblin et al. 2011).

In spite of evidence that failure to develop functional speech by age 5 is associated with poorer outcomes for children with ASD (e.g., Venter et al. 1992), much less research has focused on understanding nonverbal children. There is some evidence that children who have not developed language by age 5 are more impaired on early measures of social, communication, and imitation skills (Thurm et al. 2006). However, there has not yet been enough research on nonverbal individuals to know whether they may represent a useful unitary subtype. Several studies have shown a high concordance rate for verbal/nonverbal status in sibling and twin pairs (e.g., Spiker et al. 2002), though results have not been consistent. However, little is known about the biological mechanisms underlying the failure to acquire spoken language (Tager-Flusberg et al. 2011).

Repetitive Behaviors Subtypes

The domain of restricted, repetitive behaviors (RRBs) encompasses a variety of behaviors, ranging from repetitive sensorimotor behaviors (RSM), such as hand and finger mannerisms, to insistence on sameness (IS, e.g., difficulties with changes in routine). Factor analyses of the Autism Diagnostic Interview-Revised support a division of these subtypes of RRBs (Rutter et al. 2003).

While RSM behaviors are frequently associated with lower cognitive and adaptive functioning, IS has been shown to be relatively independent of other phenotypic features (see Richler et al. 2010 for review). Differences in correlates and predictors of change, as well as differences in patterns of change for each subtype of RRB, provide further evidence for distinct profiles of repetitive behaviors in persons with ASD. Several studies have demonstrated genetic associations with IS, further supporting its utility as a distinct subtype; recent evidence for a relationship between distinct genetic regions and RSMA has also been reported (see Coon et al. 2010).

Patterns of Onset

There has been a great deal of interest in patterns of onset of ASD, particularly in children who exhibit a loss of language and/or social skills in the first few years of life. Pickles et al. (2009) provide evidence that regression is highly specific to ASD and suggest that the phenomenon underlying loss may be related to brain development in a subtype of autism. In a sample of multiplex families in which both affected family members had a history of regression, Molloy et al. (2005) found evidence of linkage on 7q and 21q, including regions containing genes expressed in fetal brain. However, several studies have reported that, by later childhood, children with a history of regression do not differ from children without regression on a variety of outcome measures, including intellectual functioning, symptom severity, adaptive behaviors, seizures, and gastrointestinal difficulties. As with language milestones, many studies have relied on retrospective parent report of regression, which may not capture the more subtle losses observed in prospective studies (Ozonoff et al. 2011).

Physical Phenotypes

In addition to subtypes defined by specific patterns of behavior, some researchers have hypothesized that physical phenotypic features may reflect abnormal processes during embryogenesis or related to the genes involved in early development of the brain stem and face (Miles and Hillman 2000; Rodier et al. 1996). Although

dysmorphic features are neither sensitive nor specific to ASD, they may provide insight into the etiological process contributing to risk and/or development of ASD, as well as the prenatal period in which exposure to a teratogen occurred (Dufour-Rainfray et al. 2011).

Miles et al. (2005) have hypothesized that children with congenital anomalies (i.e., significant dysmorphology or microcephaly) may represent an etiologically distinct subtype which they refer to as “complex autism.” In contrast, children with no evidence of dysmorphology define “essential autism.” Compared to children with essential autism, those with complex autism are more cognitively impaired and more likely to have seizures and abnormal brain structures. Children with essential autism were noted to have a higher likelihood of being male and a family history of autism as well as a higher sibling recurrence risk (taking into account specific known genetic disorders). Miles and colleagues suggest that removing children with complex autism (which include children with specific identifiable syndromes, such as Fragile X Syndrome) from linkage and sib-pair analyses will provide a more homogeneous subgroup.

Others have focused on macrocephaly and accelerated trajectories of brain growth as a putative subtype. Pierce and Eyler (2011) posit three types of brain growth in ASD: (1) children who meet criteria for macrocephaly and have persistently enlarged brains; (2) those whose brains demonstrate large changes in size relative to head circumference at birth; and (3) those who do not demonstrate dramatic changes in brain size. However, neither the mechanisms contributing to enlarged brains and/or accelerated patterns of growth nor the relationship between these subtypes and functional outcomes in ASD is well understood (see Miles 2011; Pierce and Eyler 2011). Associations with genes implicated in other disorders (e.g., PTEN) have been demonstrated in children with autism, suggesting that studying the overlap between autism and other genetic disorders associated with macrocephaly may further the understanding of this subtype (Miles 2011). Further studies of the developing brain at the cellular and molecular level will be

important to gain insight into gene expression and mechanisms contributing to accelerated patterns of brain growth (Pierce and Eyler 2011).

In addition to physical phenotypic features, a large body of research has investigated neurochemical subtypes in ASD. One neurotransmitter that has received a significant amount of interest is serotonin (5-HT). Since early studies demonstrated that children with ASD had higher levels of whole blood 5-HT, numerous studies have sought to understand the role that 5-HT may play in ASD (see Posey et al. 2011). Serotonin challenge studies have demonstrated differences in both neuroendocrine function and behavioral symptoms (e.g., increased repetitive and self-injurious behaviors) in some participants with autism compared to controls. In contrast, studies examining the effects of selective serotonin reuptake inhibitors (SSRIs) on reducing RRBs have had mixed results (see King et al. 2009). With respect to underlying mechanisms, genes associated with whole blood 5-HT levels have been posited to play a role in autism susceptibility. Numerous studies have also indicated associations between the 5-HT transporter gene (SLC6A4) and autism, though the region implicated has varied across studies. Results suggest a complex relationship between this gene and autism; it is possible that associations with the short or long allele may represent two differing subtypes (which may explain the variability in effectiveness of SSRIs). Nonetheless, associations between SLC6A4 variants and more severe impairments in nonverbal communication and repetitive behaviors, as well as increases in cortical gray matter, suggest that this gene may increase susceptibility to autism in certain groups of children (see Posey et al. 2011; Veenstra-VanderWeele and Anderson 2011).

Sex

Many researchers have hypothesized reasons for the discrepancy in prevalence of ASD in males versus females, suggesting that affected males and females may demonstrate different cognitive or behavioral phenotypes. Early studies comparing sexes reported that females with ASD were more impaired than males in cognitive functioning (see

Hartley and Sikora 2009 for review). Recent research has begun to suggest that sex differences in cognitive ability may be present in families with one child with ASD and one or more unaffected siblings (i.e., simplex samples), but not multiplex samples (i.e., families with more than one child with ASD; Banach et al. 2008; Spiker et al. 2002).

Studies examining sex differences in ASD-related impairments have provided mixed results. While some studies have found no differences between males and females, others have suggested that, after controlling for cognitive functioning, females may demonstrate milder ASD-related impairments, particularly in terms of RRBs and imitation and play skills (see Hartley and Sikora 2009). Interestingly, behaviors comprising IS have been shown to be relatively independent of sex (Hus et al. 2007; Richler et al. 2010). Retrospective parent report of behaviors during the preschool years suggests that males may have more impaired social and communication skills than females, whereas parental reports of their child's current functioning at older ages indicated that females had more social and communication difficulties than males; other studies reported no differences (see Hartley and Sikora 2009 for review). Although findings with respect to RRBs are somewhat more consistent, it is important to note that these findings have been limited to a few studies of repetitive behaviors in toddlers or preschool- to school-age children. Thus, sex-RRB associations may be somewhat different in adolescents and adults. In contrast, studies examining social and communication impairments tended to have a somewhat wider age range, which may explain the variability in results. Moreover, measures used to diagnose ASD have not been specifically validated in female samples and may not fully capture the behavioral variability demonstrated by females with ASD (Huerta et al. 2011).

There is some evidence for sex-based etiological differences, though results have also not always been consistent. Genetic studies have indicated specific linkage associations with male-only families and others with families including females (e.g., Lamb et al. 2005; Stone et al.

2004). Furthermore, proportion of individuals carrying de novo CNVs is lower (2:1 male to female) than the overall ratio of affected males to females in the population (Xu et al. 2008).

Responders to Treatment

Paralleling the behavioral heterogeneity observed in ASD, there is a great deal of variability in response to treatment. Some researchers have begun to try to understand what factors may influence a child's responsiveness to a given treatment. In young children with autism, baseline child characteristics such as IQ, language level, interest in objects/activities, and initiation of joint attention have predicted response to different treatments. Importantly, certain interventions have been differentially predicted by these characteristics. For example, children who initiated joint attention prior to treatment made more gains in response to responsive education and prelinguistic milieu teaching (REPM), a naturalistic behavioral language intervention; in contrast, children with more limited joint attention skills responded better to the picture exchange communication system (PECS), a structured augmentative communication intervention (see Schreibman and Ingersoll 2011 for review).

Although subgroups of treatment "responders" (i.e., those who have made the most gains in response to receiving an intervention) have been identified based upon behavioral characteristics, because these characteristics are often defined relative to the "nonresponders," it is difficult to know how to define these subtypes outside of the context of the intervention study. That is, if we wanted to decide whether to refer a child to REPM or PECS, at what point do we decide that his or her level of joint attention skills is sufficient to suggest response to REPM or impaired enough to recommend that PECS may be more appropriate? While clearly there is no sufficient data to inform such clinical decisions just yet, studies that did not find expected moderating effects of child characteristics (e.g., joint attention) speculate that the absence of effects may be due to the behavior not being sampled in a sufficient number of contexts (Carter et al. 2011).

Current Knowledge

The goal of subtyping in autism – reducing phenotypic heterogeneity to produce groups more likely to share a common etiology or to predict response to treatment – seems logical. However, this approach has not always yielded the anticipated results, particularly with respect to identifying behaviors that reflect distinct etiologies. While some studies using subtypes to stratify samples have shown increased associations in genetic studies and identified QTLs related to particular subtypes, results have varied. Sometimes associations have not been significant, whereas in other studies, areas implicated have differed. On the other hand, defining subtypes of “responders” to different treatments has yielded promising results in the sense that some behaviors seem to differentially predict responses to certain treatments. However, thus far, only a few studies have characterized “responders” to treatment; many of these subtypes have yet to be replicated, and more research is needed to determine how “responders” to a given treatment respond to similar types of interventions (e.g., naturalistic interventions delivered by a therapist vs. a parent).

Small sample sizes present a significant challenge in the interpretation of discrepant results across studies (Charman et al. 2011). As noted above, finding subtypes that are independent of other characteristics, such as age and IQ, has also been challenging. An additional concern is whether the instruments used to define subtypes result in accurate classification.

Future Directions

Autism research has rapidly expanded over the last several decades, and the development and refinement of diagnostic measures now widely used across studies will facilitate our investigations of subtypes in ASD. Efforts should be made to establish subtypes using multiple measures (i.e., direct observation and parent report), with a focus on current information or corroborating information from retrospective reports with prior documentation whenever possible. The formation

of multisite collaborations and national databases, such as the Simons Foundation Autism Research Initiative (SFARI) and National Database for Autism Research (NDAR), will further promote these types of studies by providing larger samples and increased statistical power. However, we must be cognizant of factors that may influence interpretation of our results from these studies, such as ascertainment biases and site-specific effects. Thus, it will also be important for investigators conducting population-based studies to compile their samples to allow for sufficiently sized samples in which to test subtypes. Collaboration across longitudinal studies is also needed to allow examination of subtypes across several points in time as well as to take a developmental approach to identify subtypes based upon changes in behavior over time (Richler et al. 2010).

With advances in technology providing more sophisticated and sensitive measures of biological mechanisms, our understanding of how brain systems relate to behavior in both clinical and nonclinical samples has increased exponentially in the last decade, thereby enhancing our ability to investigate how behavioral subtypes in ASD may relate to neurobiological mechanisms (Charman et al. 2011). It is important that we use this knowledge to begin to draw and test hypotheses as to how some of the noted genetic variations may influence the behavioral phenotypes with which they are associated. Although some studies have begun to investigate how genes implicated in autism may affect neural mechanisms, there is still a great deal of interest in connecting behavior with particularly genotypes, which overlooks the complexity of the relationship between genes and behavior. It will be important for future investigations of subtypes to examine how gene expression influences brain structure and function to produce behavior in particular groups of individuals as well as how interactions between genes and between genes and the environment influence the brain (Abrahams and Geschwind 2008).

As behavioral subtypes are defined, it is important to remember that not all subtypes will be strongly associated with specific genotypes (Meyer-Lindenberg 2010). Thus, it is also

important that future efforts be made to investigate the clinical utility of a given subtype (e.g., whether certain behavioral subtypes are differentially responsive to particular types of treatment). To facilitate the identification of subtypes of “responders” to treatment, it may be necessary for intervention researchers to establish an agreed upon set of measures that will be considered as potential moderators to treatment. Similar measures across studies will facilitate the establishment of clear-cut parameters to define subtypes of treatment “responders.” Clearly defined subtypes will be particularly important in translating these results to clinical practice, as references to “more impaired skills” relative to the “nonresponders” are not useful in the context of deciding whether a young client is likely to benefit from a given intervention. Furthermore, requiring all studies to collect similar information will allow for comparison of how a subtype of “responders” to one treatment may benefit from other interventions. This would allow for the treatments to which the child is least likely to respond to be “ruled out” while still providing options that can then be considered with respect to other factors influencing response to treatment (e.g., parent and family characteristics, cultural factors, etc.; see Schreibman and Ingersoll 2011). It is also important to highlight that, in addition to defining subtypes of “responders,” significant efforts must also be dedicated to understanding “nonresponders” and to ensure that alternative treatments are identified for these groups. Future studies should also examine treatment response in older children and may consider examining subtypes of children who benefit from group interventions, such as social skills groups.

The search for subtypes to decrease heterogeneity in ASD may lead to a better understanding of the pathophysiology contributing to this complex disorder and enhance our ability to recommend the most appropriate treatments for certain groups of children. While much research has been done in this area, few subtypes have been definitively linked to biological mechanisms and there is not yet sufficient data to clearly define parameters of child characteristics predicting response to treatment. Research in the next decade will be

crucial to determining whether and how subtypes can be used in clinical practice.

Definition

Factors important for improving the outcomes of individuals on the autism spectrum engaging in competitive or open employment.

Historical Background

Individuals on the autism spectrum bring unique strengths and abilities to the workplace and often perform well in job tasks that require a high degree of accuracy in visual perception, systematic information processing, and precise technical abilities (Dreaver et al. 2019). While the employment support needs of this group are diverse, given the right supports and capitalizing on their strengths, individuals on the autism spectrum can be successfully employed in a variety of competitive work environments (Hendricks 2010). Work is a source of economic independence with many

benefits beyond financial gain, including positive effects on physical and mental health, a sense of accomplishment, opportunities for socialization and community engagement, and facilitating a contribution to society, with less reliance on government funding (Scott et al. 2017). However, for many individuals on the autism spectrum, the process of finding and securing a job is a challenging process, often resulting in unemployment. Unemployment rates for individuals on the autism spectrum are higher than that of individuals with other disabilities, and the general population, with these poor employment outcomes observed internationally (Black et al. 2019). Even when individuals on the autism spectrum are employed, it is often in positions well below their education and skill level, working for fewer hours and earning less wages per week compared to those with other disabilities (Shattuck et al. 2012).

Unemployment and underemployment may be attributed to the core characteristics experienced by those on the autism spectrum, including difficulties in social reciprocity and communication, and restricted or repetitive interests or behaviors (Hendricks 2010). While the individual difficulties experienced by people on the autism spectrum in obtaining a job may vary, many find it challenging to promote themselves in a traditional interview, flexibly adjust to new work environments and routines, plan and manage a multi-task workload, respond to unexpected changes in the workplace, recognize expected social norms and meet the communication demands of the workplace (Hendricks 2010; Richards 2012; Shattuck et al. 2012). Workplace settings can be complex, generally relying on self-management skills to navigate and cope with workplace demands. These environments, coupled with a pervasive lack of awareness and understanding in the workplace, and inadequate accommodations underpin the need for individualized vocational support for people on the autism spectrum (Richards 2012).

The high rates of unemployment among individuals on the autism spectrum suggest that factors beyond core characteristics are influencing their employability. It is likely that a variety of environmental factors are barriers to work

participation, including a lack of specific vocational support services, traditional job advertising and interviewing processes, and limited workplace accommodations (Scott et al. 2017). While vocational support services aim to improve employment outcomes by assisting individuals on the autism spectrum with recruitment, the interview process, workplace accommodations, and ongoing support, they remain less than optimal (Nicholas et al. 2014). Vocational support services often overlook social support needs, on-the-job training required by employees on the autism spectrum, and the level of education, support, and training required by employers and coworkers to create an inclusive workplace (Dreaver et al. 2019). These services also have a tendency to treat the needs of individuals on the autism spectrum homogeneously, failing to consider the unique and variable profiles of autism (Richards 2012). Another barrier to employment is employers' attitudes toward hiring and supporting individuals with disabilities (Hernandez and McDonald 2010). Employer attitudes in the workplace are well-recognized as influencing their hiring decisions (Unger 2002). Positive employer attitudes are associated with larger organizations, previous experience working with individuals with disabilities and the perceived benefits of retaining a qualified, reliable employee with low rates of absenteeism (Unger 2002). In contrast, negative employer attitudes are influenced by a lack of knowledge regarding disability, misperceptions relating to the unknown additional costs associated with supervision, training, and workplace accommodations and concerns over lost productivity (Hernandez and McDonald 2010). A recent cost-benefit study addressed employers' misperceptions and demonstrated that the cost of employing an individual on the autism spectrum is similar to that of neurotypical employees, and is not associated with any additional costs over and above that associated with a new employee (Scott et al. 2017). In fact, supporting the employment of individuals on the autism spectrum significantly decreases their lifetime reliance on government funding and reduces the costs associated with loss of productivity (Jacob et al. 2015).

For individuals on the autism spectrum, the desire to work is no different than those of the general working population. However, the potential for individuals on the autism spectrum to engage and contribute to the workplace remains untapped, highlighting the need for greater opportunities to engage in meaningful and competitive employment (Dreaver et al. 2019; Hendricks 2010). Employers have the potential capacity to create such opportunities and remove barriers to work participation by implementing workplace modifications, leading workplace culture, diversifying the workplace, and implementing organizational policies and practices (Erickson et al. 2014). Given the heterogeneity in the support needs of individuals on the autism spectrum in finding and maintaining employment, and the complex dynamics of the workplace environment, the factors required to enable employment success are likely diverse in nature. In order to understand these factors, it is essential to consider employment success as a combination of personal and environmental factors working together, rather than independently, to create the best fit in the workplace.

Current Knowledge

Current evidence regarding employment interventions for adults on the autism spectrum support their effectiveness in improving vocational skills, executive functioning in relation to job performance, and employment status outcomes (Hedley et al. 2016; Scott et al. 2018b). Despite the majority of these interventions having the collective purpose of improving employment outcomes, they are primarily impairment-focused, targeting specific characteristics associated with autism, such as social-communication difficulties and behaviors in the workplace, with little consideration of environmental influences (Scott et al. 2018b). There is an increasing amount of evidence suggesting that rather than only focusing on the individual and their intrinsic challenges to finding and securing employment, addressing changes in the environment may be an important enabler for employment success of individuals on

the autism spectrum (Hedley et al. 2016; Nicholas et al. 2018; Scott et al. 2018b). Therefore, it is critical to consider factors that enable employment success from both a personal and environmental perspective.

Personal Factors

Job Match

Both individuals on the autism spectrum and employers have highlighted job matching as underpinning success in finding and maintaining employment (Dreaver et al. 2019). Job matching is described as the process of establishing a “good match” between the individual on the autism spectrum, in terms of the skills, abilities, strengths and interests, and the job. General characteristics of a “good” job match include the following: (1) recognition of, and opportunity to, build on the skills and special interests of the individual; (2) predictable and structured work tasks; (3) adequate time for learning new tasks; (4) flexible work schedules; and (5) opportunities for growth (Dreaver et al. 2019; Müller et al. 2003). It is important to consider job matching from a holistic perspective, i.e., considering the individual’s skills, abilities, and interests and how these can be harnessed in the workplace, as well as the challenges of traits associated with autism. Vocational support services have a responsibility to ensure that individuals on the autism spectrum are matched to a job based on their skills and abilities required for the job and worksite. They also need to ensure that these individuals are “job-ready” through developing the necessary interpersonal skills and behaviors to meet performance and workplace expectations (Dreaver et al. 2019; Müller et al. 2003). Using a strengths-based approach is a useful way of “profiling an individual’s barriers and facilitators in acquiring a job and mitigating their weaknesses by promoting and supporting their strengths” (Scott et al. 2018b, p. 894). Recent literature is advocating for a strengths-based approach, whereby special interests of individuals on the autism spectrum are utilized in promoting workforce integration (Goldfarb et al. 2019).

Environmental Factors

Employers and Coworkers

Employers are a key environmental factor in the employment process, with their attitudes, management practices, and policies critical in facilitating work participation of individuals on the autism spectrum (Erickson et al. 2014; Unger 2002). However, employers remain a largely untapped resource in the work environment given their potential role in hiring decisions, creating employment opportunities, and providing effective supports to individuals on the autism spectrum (Hagner and Cooney 2005). Given the diverse and individualized workplace supports required by individuals on the autism spectrum, employers need to be well equipped to provide adequate support that encourages successful work participation. If the necessary support is not provided, there is a risk that employers and coworkers will rely on their preconceived ideas, attitudes and stigma toward disability in the workplace to guide their decision-making (Dreaver et al. 2019; Unger 2002). An understanding of autism by employers and coworkers has been identified as a key factor in developing positive workplace relationships (Dreaver et al. 2019). Increased knowledge of autism through autism awareness training and education, as well as open-mindedness to diversifying the workforce, has been associated with reduced workplace conflicts and misunderstandings. As a result, employees on the autism spectrum have experienced an increase in confidence in their workplace relationships, resulting in feeling “accepted” and included (Dreaver et al. 2019; Hagner and Cooney 2005; Müller et al. 2003). Inclusive and supportive workplaces are considered significant factors in determining job satisfaction and retention. Therefore, employers and coworkers who are knowledgeable about autism, supportive and flexible in their practices, and who foster positive relationships are influential in their contribution to the employment success (Dreaver et al. 2019; Hendricks 2010; Nicholas et al. 2018).

Workplace Accommodations

Workplace accommodations are a critical component of employment success. Many workplace challenges encountered by employees on the autism spectrum can be mitigated by implementing a variety of workplace accommodations during both pre-employment and once employed (Black et al. 2019; Khalifa et al. 2019). To successfully navigate these challenges, effective management practices are required, whereby employers identify problems that arise in the workplace promptly, determine the most effective strategies or accommodations required, recognize when and/or whether to implement them, and supervise the outcomes accordingly (Hagner and Cooney 2005). Often employers are quick to identify problems, such as challenging behaviors or difficulties following instructions, yet lack the expertise and knowledge in identifying what strategies to implement to assist their employees on the autism spectrum. In order for workplace accommodations to be effective, employers require support and training from autism-specific or general disability vocational service providers to upskill them in delivering individualized supports (Dreaver et al. 2019; Müller et al. 2003). An increase in employer knowledge and understanding of autism increases their capacity to identify and implement appropriate strategies (Dreaver et al. 2019; Scott et al. 2018a). This is important as workplace accommodations for employees on the autism spectrum may include (1) *social support strategies* (e.g., interpreting instructions, understanding job task expectations, teamwork); (2) *adaptive strategies* (e.g., establishing routine and structure in work tasks, alternative job interviews); (3) *cognitive strategies* (e.g., problem-solving strategies, stress management); (4) *physical strategies* (e.g., accommodations to sensory demands of the environment such as noise and light); and (5) *technology-based strategies* (e.g., use of technology-based tools or devices to improve workplace performance by prompting, directing, and managing tasks) (Dreaver et al. 2019; Khalifa et al. 2019; Müller et al. 2003).

Vocational Support Services

Workplace accommodations are also addressed through vocational support services and

employment programs. Vocational support services address the unique challenges confronted by individuals on the autism spectrum in employment, while advocating for their strengths and abilities in the best-suited job and providing ongoing support to both the employee and the employer in the process (Müller et al. 2003). These support services are accessed by individuals on the autism spectrum throughout the employment process and play a pivotal role in securing and retaining a job (Nicholas et al. 2014). Individuals on the autism spectrum who receive job readiness training, job search assistance, job placement services, and ongoing on-the-job support through vocational support services are significantly more likely to achieve and sustain competitive employment, with increased working hours and wages (Hedley et al. 2016; Hendricks 2010; Nicholas et al. 2018). In addition, employment programs, such as the TEACCH program, Project SEARCH, and the National Autistic Society Prospects all focus on improving employment outcomes either through the use of job coaches, internships, or supported employment services (Hedley et al. 2016). Overall, vocational support services and employment programs are integral in enabling employment success and are often considered as a “bridge” between individuals on the autism spectrum and the employer.

Family

The family system, particularly parents or caregivers of individuals on the autism spectrum, plays an influential role in employment outcomes (Nicholas et al. 2018). Many parents are strong advocates for their adult children and often engage in the employment process, beginning in high school with their child’s transition plan into adult life. Parents are key enablers in achieving vocational success, with many assisting their adult children in searching for job opportunities, approaching local community businesses for potential jobs, creating a job in a family business, and navigating services (Nicholas et al. 2018). This prolonged support and advocacy facilitates achieving employment outcomes for individuals on the autism spectrum.

Policy, Procedures, and Practices

Policies and practices related to the employment of people with disabilities are designed to remove barriers and facilitate work participation. Policies and practices that focus on recruitment and hiring, disability-related awareness training for staff, accessible accommodations, and retention have been shown to reduce barriers in the workplace for employees with disabilities (Erickson et al. 2014). While employment policies and practices vary globally, those, which are characterized by increased government support for vocational support services and employment programs, with strong employer obligations, universal coverage, and comprehensive and accessible incentives, have higher employment rates of people with disabilities (Black et al. 2019). Although policies and practices consider employment outcomes of individuals on the autism spectrum from a broader perspective, they have the power to facilitate work participation at an individual, organizational, and societal level (Erickson et al. 2014).

Future Directions

While it is increasingly clear that environmental supports and modifications, job-matching, and harnessing strengths of individuals on the autism spectrum are essential to improving employment prospects, future efforts must be made to support organizations and employers in this task.

A paradigm shift away from focusing on individual deficits and instead using a biopsychosocial approach, such as the International Classification of Functioning, Disability and Health (ICF) that considers the environment alongside an individual’s strengths and difficulties profile, is needed to support the employment of individuals on the autism spectrum (Black et al. 2019). While there is increasing recognition that addressing the environment is important for success, there are limited interventions that directly target this important factor (Scott et al. 2018b). The Integrated Employment Success Tool™ (IEST) is one evidence-based intervention that targets the environment. The IEST™ seeks to provide employers across a variety of workplaces with the tools necessary to support employees on the

autism spectrum (Scott et al. 2018a). Future research should continue to develop and evaluate interventions that target the workplace environment.

Ensuring a match between the individual and the work task is an important factor for success. This may be a daunting task for employers, who may have difficulty understanding the unique strengths and difficulties profile of each of the employees on the autism spectrum. Tools and supports which assist employers to create an environment and job tasks which harnesses individual unique strengths are needed to facilitate a job-match. It must, however, be noted that within current labor markets, ensuring a match between a job and an individual's interests is not always possible for all employees at all times. Goldfarb et al. (2019) suggest that Social Determination Theory may play a critical role in addressing this potential misalignment between the job and an individual's interests, proposing that extrinsic motivators (such as salary), and ensuring that individuals have the opportunity for choice or autonomy, positive social relatedness, and feelings of competence may contribute to work motivation. An integrative approach, combining a strength-based approach that strives for a person-job match, along with Social Determination Theory, may work to promote long-term motivation and employment success. Future research should seek to understand how employers can not only harness an individual's strengths but also how employers and workplaces can ensure that the basic human needs of autonomy, social relatedness, and competence can be met in the workplace (Goldfarb et al. 2019).

Providing early work experience, for example, in high school, may be an important first step to employment for individuals on the autism spectrum. Work experience can provide youth on the autism spectrum with insights into their own unique strengths and difficulties profile in the workplace, enabling them to explore their interests, develop skills, and gain important insights into the workplace (Lee et al. 2019). Opportunities for work experience should be provided to individuals on the autism spectrum, with a focus on how early work experience may be integrated into schools.

Suicidality in Children and Adolescents with Autism

Kimberly Ellison¹ and James C. McPartland²

¹Yale Child Study Center, New Haven, CT, USA

²School of Medicine, Child Study Center, Yale University, New Haven, CT, USA

Definition

Suicide may be defined as death caused by a self-inflicted injury with the intent to kill oneself. The umbrella term, suicide, encompasses a spectrum of classifications varying in degree of intensity from suicidal ideation (thoughts of wanting to end one’s life) to suicide attempts (completed or aborted efforts).

Historical Background

Research in autism spectrum disorders (ASD) is a nascent field compared to other psychiatric disorders. With recent recognition of more cognitive

able forms of ASD (e.g., Asperger's Disorder in the *Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition [DSM-IV]*), there has been greater focus on comorbidities, including mood disorders and suicide. In this regard, suicide is a minimally studied and poorly understood phenomenon in ASD.

Current Knowledge

In the United States, suicide is the 2nd leading cause of death for children and adolescents between the ages of 10 and 17 (Centers for Disease Control 2014). Specific demographic variables are considered risk factors for suicide. In nonclinical populations, older age (within the period of adolescence) and male sex increase the risk of suicide five-fold (Centers for Disease Control 2015). In addition to age and gender, being victimized or socially isolated by peers and having co-morbid psychiatric disorders, such as depression and anxiety, are risk factors for suicidal ideation and suicidal behavior in typical children and adolescents.

Suicide and Autism. A limited number of studies have investigated suicidal ideation and suicidal behavior in youths with ASD. These studies have yielded varying rates of suicidality. In a Japanese sample of 94 adolescents hospitalized for a suicide attempt, 12 (13%) met the diagnostic criteria for ASD and of those 12, five (42%) had previous histories of suicide attempts. Six of the twelve adolescents (50%) had a history of psychiatric difficulties (Mikami et al. 2009). Similarly, in a small sample of 10 adolescents, 50% endorsed clinically significant levels of suicidal ideation (Shtayermman 2008). Other studies fail to corroborate such a high rate of suicidality in ASD; for example, 20 of 102 (20%) youths diagnosed with ASD and co-morbid anxiety endorsed suicidal thoughts and behavior on a self-report measure, and 11 of the 102 (11%) displayed having suicidal thoughts (Storch et al. 2013). The prevalence of suicidal thoughts in children and adolescents with ASD has also been explored through parent report. In comparison to 0.5% of mothers of typically developing controls ($N=186$), between 13% and 14% of mothers of children with autism

($N=791$) rated their child as having suicidal ideation or attempts as being “sometimes to very often a problem” (Mayes et al. 2013). Given the limited and inconsistent research on suicide in ASD, this represents an important area for further investigation.

Risk Factors

Demographic Variables

Age, gender, race, and socioeconomic status are demonstrated risk factors of suicidal ideation or attempts in children with autism (Mayes et al. 2013). More specifically, youths with ASD were found to be at a higher risk for suicidal ideation or suicidal behavior if they were found to be: 10 years of age or older, of the male sex, of the African American or Hispanic race, and/or of a lower socioeconomic status. Children with ASD over the age of 10 endorsed having suicidal ideation or attempts three times more than children younger than 10 years of age. The frequency of suicidal ideation or attempts was twice as high in males with ASD than in females with ASD (Mayes et al. 2013).

Symptom Severity

Studies have yielded conflicting results about the relationship between the severity of autism symptoms and frequency of suicidal ideation or attempts. Children diagnosed with Autistic Disorder were more likely to have suicidal thoughts or behaviors than those diagnosed with Asperger Disorder (Storch et al. 2013). Additionally, strong negative correlations have been found between level of suicidal ideation and severity of autism symptoms (Shtayermman 2008). This relationship between symptom severity and suicidal ideation is not evident in all samples. Mayes and colleagues (2013) found no relationship between frequency of suicidal ideation or attempts and autism severity.

Comorbidities

Suicidal ideation and suicide attempts are associated with multiple psychiatric illnesses in both typical development and ASD including: depression, anxiety, bi-polar, and posttraumatic stress disorder (PTSD). Depression and anxiety are the

leading co-morbid diagnoses in adolescents with ASD (Storch et al. 2013). Mayes et al. (2013) examined rates of depression in a sample of 350 children and adolescents with ASD (ages 6–16); they found that 54% of youths with higher functioning autism and 42% of youths with lower functioning autism were reported (by their parent) to exhibit depressed mood. Additionally, depression, impulsivity, and behavioral difficulties were significant predictors of suicidal ideation or attempts in children with ASD (Mayes et al. 2013). Similarly, in a sample of 23 children and 14 adolescents with Asperger's Disorder, 35 children and adolescents had at least one additional psychiatric diagnosis (Mukaddes and Fateh 2010). The most common psychiatric disorders for this group were anxiety disorders (54%), disruptive behavior disorders (48%), and mood disorders (37%). Furthermore, 42% of the adolescents were found to have suicidal behaviors; these individuals were diagnosed with both a mood and an anxiety disorder (Mukaddes and Fateh 2010). Other research has found similar rates of suicidal thoughts and behavior in youths with ASD and anxiety (11%) as compared to neurotypical youths without anxiety (14%), suggesting that suicidality is present to a similar degree (Storch et al. 2013; Wunderlich et al. 2001). It has also been found that having a comorbid diagnosis of PTSD is associated with increased risk of suicide in youths with ASD (Storch et al. 2013).

Bullying

Bullying has been defined by researchers as the repeated exposure to aggressive acts, directly or indirectly, over time that are intended to harm the individual physically, emotionally, or socially (Sofronoff et al. 2011; Blake et al. 2012). The act of bullying can come in many forms including: name calling, spreading rumors, purposeful exclusion from events or activities, physical aggression, and targeted cyber-attacks. A review of research investigating suicide and bullying among youths in the general population revealed that victims of bullying exhibited higher levels of suicidal ideation and were more likely to attempt suicide (Klomek et al. 2010; Geoffroy et al. 2016). Furthermore, being bullied at school was found

to be a significant risk factor for suicidal thoughts and behaviors, independent of other established risk factors such as depression, socioeconomic status, and biological sex (Kaminski and Fang 2009).

It has been shown that children and adolescents with ASD are at increased risk of peer victimization, including social isolation and bullying (Locke et al. 2010; Cappadocia et al. 2012). Repeated victimization was found to be significantly higher for both elementary and middle school students with ASD (Blake et al. 2012). Moreover, research has indicated that the rate at which youths with ASD are victimized varies and this variation may be influenced by the perspective of the informant and their ability to report accurately. Bullying has been reported at higher rates by both by children with ASD and their mothers when compared to neurotypical youths and their mothers (Zeedyk et al. 2014). Furthermore, youth's self-report of the emotional impact of bullying was significantly higher for the ASD group compared to neurotypical youths (Zeedyk et al. 2014). Additionally, in a general education setting, teachers reported higher rates of bullying of children with ASD compared to peer and self-reports (Van Roekel et al. 2010).

There are a number of factors that may contribute to the increased rate of bullying experienced by students with ASD. This increased risk may be due to the child's limited ability to understand the social world as well as having other psychiatric disorders present. Children with ASD who have experienced more victimization were more likely to be rated by their parents have having other psychiatric difficulties such as higher levels of anxiety than those children who experienced no peer victimization (Cappadocia et al. 2012). It will be critical for future research to determine whether the increased risk of bullying in ASD is associated with an increased risk for the development of suicidal thoughts and behaviors.

Assessment

There is not currently a specific assessment tool to measure specific suicide risk in individuals with ASD, and there are numerous challenges to

assessing risk in this population. First, youths with ASD commonly have difficulties with expressive language, and this is often particularly pronounced for social-emotional matters, complicating assessment of emotional distress (Losh and Capps 2006). Paired with reduced insight into one's own emotions, these factors decrease the effectiveness of standard risk assessment methods in this population.

Prevention

It is recommended that parents and professionals working with children and adolescents on the autism spectrum take thoughts or mentions of suicide very seriously. Any comments made regarding thoughts of wanting to hurt or kills oneself should be considered significant and promptly brought to the attention of a qualified mental health professional or emergency medical center. Aware of predisposing risk factors, such as a family history of suicide attempts, can support early recognition of suicidal ideation prior to the emergence of suicidal behaviors.

In summation, though suicidality in autism is of great relevance to public health, existing research is scant. Particular areas requiring further investigation include assessment of suicide risk in ASD and strategies for psychoeducation for children and adolescents with ASD.

Future Directions

The aforementioned work highlights multiple topics that must be investigated in the future studies. It will be important to understand how children and adolescents with ASD think about and understand the concept of suicide. This will inform more accurate assessment of risk. Additional exploration of risk factors (e.g., social isolation, comorbid psychiatric disorders), protective factors, and the interplay between these factors is needed to shed light on high suicide prevalence rates for children and adolescents with ASD compared to the general population.

Suicide Rates in Adults with Autism

Mohammad Ghaziuddin
University of Michigan, Ann Arbor, MI, USA

Definition

Suicide can be defined as the deliberate taking of one's life. A leading cause of death worldwide, it is the most extreme form of a range of behaviors which include suicidal thoughts and attempts. There is no single cause of suicide. Risk factors include presence of mental illness particularly depression, family history of suicide, substance abuse, chronic medical illness, and exposure to

stressful life events. While suicidal attempts occur more commonly in females, completed suicide is more common in males.

Autism and Suicidal Behavior

Prevalence

Suicidal behavior is being recognized as an emerging problem in persons with autism spectrum disorders (ASD), particularly in those with a normal IQ (high-functioning autism, HFA). Although it occurs in both children and adults with ASD, relatively little research has been done on the clinical correlates and mechanisms underlying suicidal behavior in this population. Most of the research on this topic has been done in clinical samples. Prevalence rates based on epidemiological studies of suicidal behavior in individuals with ASD are not known.

Completed Suicide

While suicidal behavior has been described in several recent studies, reports of *completed suicide* in persons with ASD are uncommon. Most of these have involved persons with HFA or those with mild to moderate degree of intellectual disability (ID) with relatively good verbal skills and have been reported in the newspapers. For example, Nikki Bacharach, the 40-year-old daughter of the composer Burt Bacharach, committed suicide by suffocating herself using a plastic bag and helium. She reportedly had a diagnosis of Asperger syndrome (AS) with depression (2013). In a recent Italian study of 26 adults with ASD, two (7.7%) committed suicide; one had PDDNOS, schizophrenia, and alcohol abuse by jumping from a bridge and the other with AS and schizophrenia, by dismemberment (see Raja et al. 2011). In the USA, a recent problem has been that of mass school shootings, characterized by indiscriminate violence against others, followed by suicide of the perpetrator. At least two of the individuals involved in such incidents were known to have been diagnosed with ASD during their lifetime (Farrell 2016; Ghaziuddin 2013).

Indirect evidence of completed suicide in this population also comes from mortality studies of individuals with autism. For example, Mouridsen and colleagues (2008) examined the causes of death in a clinical sample of patients with ASD, aged 2–17 years, in Denmark. They found that the mortality rate was increased in persons with autism compared to that of the rest of the population. Among the 26 deaths recorded, 5 patients died from unnatural causes, 3 in accidents (suffocation and drowning), and 2 by suicide. Both patients who committed suicide were male of average intelligence. One, with a diagnosis of atypical autism, took an overdose of medications, while the other, with a diagnosis of Asperger syndrome, jumped to his death (Mouridsen et al. 2008). Mortality studies of autism are remarkable in suggesting not only higher rates compared to that of the general population but also pointing out the high occurrence of accidents, such as drowning and suffocation (Shavelle et al. 2001). It is possible that suicidal behavior could have contributed to some of these accidents.

Suicidal Ideation and Attempts in Adults

In her paper on Asperger syndrome, Lorna Wing described two patients who had made a suicidal attempt and another who had made suicidal statements (Wing 1981). Subsequently, Wolff and McGuire (1995) reported that out of 49 subjects with “schizoid personality disorder,” many of whom were probably on the autistic spectrum, 10 out of 17 women and 17 out of 32 men had attempted suicide, a rate higher than that in the general population (Wolff and McGuire 1995). Kato and colleagues examined the characteristics of adults with ASD presenting to the emergency room with suicidal behavior (Kato et al. 2013). ASD patients were compared with non-ASD patients on psychiatric diagnoses, frequency of suicidal attempts, and clinical features. Out of the 587 subjects who attempted suicide, 43 (7.3%) had ASD. In a survey of parents of adult children with ASD carried out by the UK National Autism Society (NAS 2001), about a third of parents reported that their son or daughter had experienced mental health problems, out of which about half suffered from depression and 8% from suicidal behavior including attempted

suicide (Barnard et al. 2001). In a recent study, Cassidy et al. (2014) explored suicidal behavior in adults with Asperger syndrome. Two-thirds of the sample reported that they had thought about committing suicide at some point, and 35% had made specific plans to kill themselves.

Suicidal Ideation and Attempts in Children and Adolescents

In a study of 537 subjects with high-functioning autism (HFA, defined as IQ 80) and 254 subjects with low-functioning autism (LFA, IQ <80), 1–16 years of age, subjects’ mothers were asked about suicidal behavior in their offspring. The 13.8% of children with autism rated suicide ideation or attempts as a problem, compared with 0.5% for typical children and 42.9% for depressed children ($\chi^2 = 55.6, p < 0.0001$). There were no differences between high-functioning and low-functioning autistic patients (Mayes et al. 2013). In a retrospective chart review of 233 patients admitted to a specialized service for children with developmental disabilities and comorbid psychiatric disorders, Hardan and Sahl found that 47 (20%) had a past or present history of suicidal ideation or attempt. Three subjects had autism and four had PDDNOS. Suicidal behavior was more common in patients with depression, oppositional defiant disorder (ODD), and post-traumatic stress disorder (PTSD) than in those with autism and profound mental retardation. The authors speculated that autism and/or profound intellectual disability acted as protective factors against suicide (Hardan and Sahl 1999). Based on a chart review, Mikami et al. (2009) reported that 12 (12.8%) out of a consecutive series of 94 adolescent patients (aged under 20 years) admitted to an inpatient unit with suicidal behavior were diagnosed with having ASD. Six cases had Asperger syndrome and six had PDDNOS. Life events, such as bullying, were common. Interestingly, depression was underrepresented in the ASD group compared to the non-ASD group (Mikami et al. 2009).

Presentation

The presentation of suicidal behavior in persons with ASD depends on the level of intelligence and verbal skills. Persons with HFA can better

verbalize their feelings and admit to suicidal thoughts and behavior (Ghaziuddin et al. 2002). A small number of adolescents with ASD, often with average level of intelligence, may present with superficial self-cutting and make repeated statements to die but show no clear suicidal intent on examination. These should be differentiated from low-functioning individuals with ASD, often with the IQ in the severe to profoundly disabled range, who indulge in repetitive self-injurious behaviors such as head banging, self-biting, and other aggressive behaviors. In the latter group, the intent to commit suicide is not expressed. The assessment of suicidal behavior in autistic persons with very low IQ is complicated. Because of communication problems, these patients cannot verbalize their feelings and may, therefore, act out in other ways, such as aggression toward self or others. When present, a history of recent change in behavior with frequent crying, regression of skills, loss of interest in pleasurable activities, and change of sleep or appetite may help in the evaluation. A family history of major mental illness and of completed suicide can further support a diagnosis of suicidal behavior. In general, however, the more intellectually disabled a person is, the more difficult it is to screen for suicidal behavior.

Causes and Risk Factors

As mentioned above, the most common cause of suicidal behavior in the general population is psychiatric illness, particularly depression. The same applies to persons with ASD. Autistic persons develop all types of psychiatric disorders across their life span, especially after puberty. Depression and other mood disorders are particularly common (Ghaziuddin et al. 2002). Both high- and low-functioning individuals with ASD may develop comorbid depression, although the signs and symptoms are relatively easy to elicit in those who are higher functioning, that is, have relatively normal intelligence and verbal skills. In addition to depression, suicidal behavior can also result from bipolar disorder which typically emerges in late adolescence and early adulthood. Suicidal behavior and completed suicide in persons with ASD have also been reported in

association with psychotic disorders, including psychotic depression with hallucinations and delusions (see Raja et al. 2011). In addition, suicidal behavior can also occur in autistic individuals with anxiety disorders. Storch et al. (2013) described suicidal behavior in 102 children and adolescents (7–16 years) with HFA and comorbid anxiety disorder. Eleven percent displayed suicidal thoughts and behaviors. An association was found between depression and a history of trauma. Other risk factors for suicidal behavior in persons with ASD include social isolation, bullying, and impulsivity. A family history of completed suicide is a known risk factor in persons committing suicide. Furthermore, there is some suggestion for shared predisposition for suicide and autism spectrum disorders (Chojnicka et al. 2013).

Management

Crisis Intervention/Inpatient Admission

The first step is to ensure the safety of the suicidal person. All suicidal threats and gestures in persons with ASD should be taken seriously. A systematic assessment should be done of the level of functioning of the individual, of the family and social circumstances, and of any precipitating or risk factors. A detailed psychiatric assessment should be performed focusing on mood symptoms. A history of previous attempts should be elicited. Depending on their level of functioning, adolescents and adults with ASD can express their suicidal thoughts and plans, if questioned in a tactful manner. Clinicians working with lower-functioning individuals with ASD should be trained to screen for suicidal behavior not only by taking a detailed history from the caregivers about changes in the mood and behavior but also by looking for any indirect evidence of suicidal intent in play and interests. If the patient is actively suicidal or psychotic, and if the family is unable to guarantee his safety, a brief admission to a specialized unit should be considered to assess the safety of the patient; clarify the reasons for the suicidal behavior; screen for psychiatric disorders; and give relief and support to the family.

Outpatient Treatment

The goal of outpatient treatment is to help the patient remain safe and gradually return to normality. By using appropriate interventions, improvement made in the hospital should be sustained. Common methods of treatment include medications and individual and family therapy. Parents should be educated to be alert to any clues of self-harm. Finally, appropriate changes should be made in the environment. For example, if the suicidal act occurs due to bullying at school, efforts should be made to involve the school authorities in the treatment program to provide support and protection to the affected person. Parents and caregivers experience severe stress when they realize, often for the first time, that their child not only has a chronic disability (autism) but also a psychiatric disorder. They may themselves need psychological support which is critical to improving the long-term outcome of the affected person.

Prevention

All suicide attempts should be taken seriously. Professional help should be sought and steps taken to minimize the risk of suicide. Caregivers should be trained to look out for clues of suicidal behavior. Those patients who have a history of suicidal behavior and those with a family history of completed or attempted suicide should be carefully observed. When care is provided at home, all necessary changes should be made to ensure safety. These include locking away guns and other weapons in the house, limiting access to pills, placing locks on the doors and windows, etc. If safety cannot be guaranteed at home or if outpatient treatment is not practical, admission to a psychiatric unit should be considered.

Conclusion

Suicidal behavior is probably underreported in persons with ASD. Reasons include a low level of suspicion on the part of clinicians and the difficulty of assessing suicidal behavior in persons

with severe deficits of communication and intelligence. Most of the research has focused on clinical samples of relatively modest size, usually of higher-functioning individuals, with limited details about their psychiatric comorbidity. It remains to be determined if the core autistic deficits raise the risk of suicide in persons with ASD or if this applies only to a subgroup of individuals within the spectrum. The relationship between the level of IQ and suicidality also needs to be clarified as also the role of family-genetic factors and life events. Despite these limitations, the findings emphasize the need for screening for suicidal behavior in all persons with autism and for undertaking systematic studies to facilitate its early detection and treatment.

Superior Temporal Sulcus Region

Kevin A. Pelphey Harris

Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Synonyms

[Superior temporal sulcus](#)

Definition

The superior temporal sulcus is the sulcus separating the superior temporal gyrus from the middle temporal gyrus in the temporal lobe of the brain. Single-cell recordings in monkeys, and neurophysiological and neuroimaging studies in humans, reveal that cerebral cortex in and near the superior temporal sulcus region plays an important role in social perception. As defined by Allison et al. (2000), social perception “refers to initial stages in the processing of information that culminates in the accurate analysis of the dispositions and intentions of other individuals.” In man and monkey, the superior temporal sulcus regions respond vigorously to biological motion (the motion characteristic of living, animate beings) including movements of the eyes, mouth, hands, arms, and whole body.

Support Trust

Tobi Gilbert Juris

Quinnipiac University School of Law, Hamden,
CT, USA

Definition

A support trust is a type of discretionary trust used for estate planning whereby the creator of the trust (the *settlor*) transfers the assets to another (the *trustee*), who then has a duty to hold and manage the assets for the benefit of a third party (the *beneficiary*). If the trust is established by a living settlor, rather than through a will, the trust acts as a will substitute and the transferred estate avoids probate and some estate taxes.

A pure discretionary trust empowers the trustee with absolute discretion to authorize any distributions the trustee considers advisable. The trustee may decide the “time, purpose and amount of all distributions” to one or more beneficiaries (POMS SI §01120.200.B.10). Because the trustee can only be compelled to distribute money from the trust under very restricted circumstances, the assets are protected against invasion by the beneficiary, or the beneficiary’s general creditors.

In contrast, a support trust grants limited discretion upon the trustee allowing distributions solely for the “comfortable support, education, health and maintenance of the beneficiary” (Leslie and Sterk 2006). “Food, shelter, education, and medical care” are eligible categories, but the trustee may still have the discretion to determine the timing and amount of assets to assign to each category (Begley and Canellos 2010).

A common type of support trust provides care for a surviving spouse in “the manner and style to which they are accustomed” (In re Estate of Brown 1987, p. 754). In other instances, a support trust can be drafted to meet the special needs of a minor child, or a mentally incompetent individual.

Special needs trusts are established to provide supplemental funds for a beneficiary who may also be eligible to receive public benefits including SSI or other government benefits. Trust fund

distributions must only supplement public funding; the beneficiary must have no control over the assets, or ability to compel distributions. Administration of such trusts can be complex, requiring specialized knowledge of the entitlement programs available over the course of the incompetent beneficiary’s lifetime.

A support trust may be an effective estate planning tool, depending on the intent of the settlor, the objectives of the trust, and the specific needs of the beneficiary. However, the trust must be carefully drafted to consider potential conflicts between the availability of trust assets to potential creditors, as well as eligibility for public assistance programs. Additionally, problems may arise such as a trustee’s breach of duty to manage the trust in “good faith,” or “in accordance with its terms and purposes,” or “in the interests of the beneficiary” (Uniform Trust Code § 801 et. seq.). This may be demonstrated when the trustee abuses the assigned discretionary power, and the beneficiary is not competent to address the breach. Therefore, one must carefully evaluate the goals of the settlor, the competence and trustworthiness of the trustee, and the long-term needs of the beneficiary in order to determine which type of discretionary trust is the best estate planning option.

Supported Employment

Paul Wehman¹ and Pamela Targett²

¹Department of Physical Medicine and Rehabilitation, Virginia Commonwealth University, Richmond, VA, USA

²Virginia Commonwealth University, Richmond, VA, USA

Definition

The term supported employment has been traced back to the early 1980s when advocates and service providers for individuals with intellectual disabilities became increasingly aware that students were not making the transition from school to the workforce. The official government definition appeared in the mid-1980s and provided the parameters of the concept that still exists today.

Supported employment means:

1. Competitive employment in an integrated setting with ongoing support services for individuals with the most severe disabilities:
 - (a) For whom competitive employment has not traditionally occurred or for whom competitive employment has been interrupted or intermittent as a result of a severe disability
 - (b) Who, because of the nature and severity of their disabilities, need intensive supported employment services from the designated state unit and extended services after transition in order to perform this work
2. Transitional employment for individuals with the most severe disabilities due to mental illness

Some of the major terms in the definition such as competitive employment and ongoing services will be examined more closely in the following

section when supported employment is described as a state's vocational rehabilitation service option known as supported employment services.

A number of models emerged over the years. The one promoted here is the individualized approach where a person with a significant disability receives one-to-one assistance with gaining or maintaining employment in his or her community, a real job for real pay, by using an array of supports provided and/or facilitated by a vocational rehabilitation professional known as a job coach or employment specialist. It has been described as a strategy for changing the mismatch between employment expectations for people with severe disabilities and the limited options in their communities (i.e., workshops or unemployment, etc.).

Historical Background

For many years, individuals with significant disabilities were served within a continuum model of vocational rehabilitation which included day centers, sheltered workshops, and transitional programs. The premise behind this approach was to teach individuals with disabilities the skills needed to become "ready to work." However, movement out of these segregated settings into employment in the community rarely took place, and eventually, the system came under criticism (Wehman 2006; Whitehead 1979). At this time, the belief that all individuals including those with significant disabilities should have the opportunity to achieve as much independence as possible including working in their communities was also beginning to flourish. In addition, a number of researchers were demonstrating that people with moderate to severe intellectual disabilities could learn complex real work tasks and furthermore that these tasks could and should be taught on the job (Bellamy et al. 1979; Gold 1972a, b, 1978; Rusch and Scutz 1979; Wehman 1981; Wehman et al. 1979), instead of in segregated settings. The approach used applied behavior analysis and systematic instruction (Test and Wood 1997). This requires breaking tasks down into stimulus response chains and using

prompting hierarchies and reinforcement to teach them (Bellamy et al. 1979).

At last, no longer were individuals with significant disabilities required to learn prerequisite skills in segregated settings prior to going to work. Instead of training an individual with a disability outside of a workplace to get ready to work (i.e., work readiness) and then locating employment, now research backed the effectiveness of a model that emphasized the effectiveness of obtaining employment first and then training the newly hired employee the skills needed on the job. In the years that followed, a number of projects were funded that demonstrated the effectiveness of training individuals with significant disabilities on the job. The results of these efforts revealed promising practices for a supported employment approach to assist individuals with developmental disabilities with employment (Vogelsberg 1990).

Again, up until this time, most individuals with significant disabilities had often been denied the option to work in their communities. Because of discrimination and oppression and unfounded beliefs regarding personal skills, capacities, and capabilities, individuals with disabilities had often been relegated to segregated environment like day centers and sheltered workshops.

Passage of legislation, such as the Developmental Disabilities Assistance and Bill of Rights Act of 1984 and Title VI, Part C of the Rehabilitation Act Amendments of 1986, in combination with systems change grants funded through Title III of the Rehabilitation Act, provided the basis for the initiation of a series of federal- and state-funded demonstration projects designed to provide opportunities and supports for individuals with severe or significant disabilities to work alongside other citizens in their communities.

Current Knowledge

Through the years, the supported employment approach has been used to assist individuals with developmental disabilities with gaining and maintaining “real work for real pay” (Wehman 2012). Although initially conceived as an

employment support service for individuals with intellectual disabilities, today supported employment has also been instrumental in assisting individuals with mental illness (Bond et al. 2001; Drake et al. 1999), traumatic brain injury (Wehman et al. 1993), autism (Howlin et al. 2005; Wehman et al. 2009), cerebral palsy, physical disabilities (Inge et al. 1998), and other disabilities (Wehman and Revell 1996).

States offer this service under the State Supported Employment Services Program which is under the Authority: 29 U.S.C. 795j–q, unless otherwise noted. What follows are the specifics about the program and the definitions from the Source: 59 FR 8331, Feb. 18, 1993, unless otherwise noted.

Under the State Supported Employment Services Program, the secretary provides grants to assist states in developing and implementing collaborative programs with appropriate entities to provide programs of supported employment services for individuals with the most severe disabilities who require supported employment services to enter or retain competitive employment (Authority: 29 U.S.C. 795j).

A state may provide services under this program to any individual if:

- (a) The individual has been determined eligible for vocational rehabilitation services in accordance with the criteria in section 102(a) (1) of the Act
- (b) The individual has been determined to be an individual with the most severe disabilities
- (c) Supported employment has been identified as the appropriate rehabilitation objective for the individual on the basis of a comprehensive assessment of rehabilitation needs, including an evaluation of rehabilitation, career, and job needs (Authority: 29 U.S.C. 795 m)

Under this program, the following activities are authorized:

- (a) Any particularized assessment that is needed to supplement the comprehensive assessment of rehabilitation needs done under 34 CFR part 361 and that is provided subsequent to

the development of the individualized written rehabilitation program. The supplementary assessment may be provided in circumstances such as the following:

1. A reassessment of the suitability of the placement is warranted.
 2. There is a change in the individual's medical condition.
- (b) Development of and placement in jobs for individuals with the most severe disabilities.
- (c) Provision of supported employment services that are needed to support individuals with the most severe disabilities in employment, such as:
1. Intensive on-the-job skills training and other training provided by skilled job trainers, coworkers, and other qualified individuals, and other services specified in Section 103(a) of the Act in order to achieve and maintain job stability
 2. Follow-up services, including regular contact with employers, trainees with the most severe disabilities, parents, guardians or other representatives of trainees, and other suitable professional and informed advisors in order to reinforce and stabilize the job placement
 3. Discrete postemployment services following transition that are unavailable from an extended services provider and that are necessary to maintain the job placement, such as job station redesign, repair and maintenance of assistive technology, and replacement of prosthetic and orthotic devices (Authority: 29 U.S.C. 795l)

The following regulations apply to the State Supported Employment Services Program:

- (a) The Education Department General Administrative Regulations (EDGAR) as follows:
1. 34 CFR part 76 (State-Administered Programs)
 2. 34 CFR part 77 (Definitions that Apply to Department Regulations)
 3. 34 CFR part 79 (Intergovernmental Review of Department of Education Programs and Activities)

4. 34 CFR part 80 (Uniform Administrative Requirements for Grants and Cooperative Agreements to State and Local Governments)
 5. 34 CFR part 81 (General Education Provisions Act-Enforcement)
 6. 34 CFR part 82 (New Restrictions on Lobbying)
 7. 34 CFR part 85 (Governmentwide Debarment and Suspension (Nonprocurement) and Governmentwide Requirements for Drug-Free Workplace (Grants))
 8. 34 CFR part 86 (Drug-Free Schools and Campuses)
- (b) The regulations in this part 363
- (c) The following regulations in 34 CFR part 361 (The State Vocational Rehabilitation Services Program): §§361.31; 361.32; 361.33; 361.34; 361.35; 361.39; 361.40; 361.41; 361.42; 361.47(a); 361.48; and 361.49

Note: Many of the regulatory provisions cross-referenced in §363.5(c) are affected by statutory changes made by the Rehabilitation Act Amendments of 1992. If these provisions conflict with statutory language, they are superseded by the statutory language. Program regulations for part 361 are being amended to implement statutory changes. When final regulations for part 361 are published, these cross-references will be corrected, if necessary

(Authority: 29 U.S.C. 795j and 711(c)):

- (a) Definitions in 34 CFR part 361. The following terms used in this part are defined in 34 CFR 369.4(b):
- Act
 - Designated state unit
 - Individual with disabilities
 - Individual with severe disabilities
 - State plan
- (b) Definitions in EDGAR. The following terms used in this part are defined in 34 CFR 77.1:
- Fiscal year
 - Nonprofit
 - Private secretary
 - State

(c) *Other definitions.* The following definitions also apply to this part:

1. *Supported employment* means:

(i) Competitive employment in an integrated setting with ongoing support services for individuals with the most severe disabilities:

(A) For whom competitive employment has not traditionally occurred or for whom competitive employment has been interrupted or intermittent as a result of a severe disability

(B) Who, because of the nature and severity of their disabilities, need intensive supported employment services from the designated State unit and extended services after transition in order to perform this work

(ii) Transitional employment for individuals with the most severe disabilities due to mental illness

2. As used in the definition of “supported employment”:

(i) *Competitive employment* means work:

(A) In the competitive labor market that is performed on a full-time or part-time basis in an integrated setting

(B) For which an individual is compensated at or above the minimum wage, but not less than the customary or usual wage paid by the employer for the same or similar work performed by individuals who are not disabled

(ii) *Integrated setting* means a setting typically found in the community in which an individual with the most severe disabilities interacts with non-disabled individuals, other than non-disabled individuals who are providing services to that individual, to the same extent that nondisabled individuals in comparable positions interact with other persons.

(iii) *Supported employment services* means ongoing support services provided by the designated state unit with funds under this part:

(A) For a period not to exceed 18 months, unless under special circumstances a longer period to achieve job stabilization has been jointly agreed to by the individual and the rehabilitation counselor and established in the individualized written rehabilitation program, before an individual with the most severe disabilities makes the transition to extended services

(B) As discrete postemployment services following transition in accordance with §363.4(c) (3)

(iv) *Extended services* means ongoing support services and other appropriate services provided by a state agency, a private nonprofit organization, employer, or any other appropriate resource, from funds other than funds received under this part, part 381, part 376, or part 380, after an individual with the most severe disabilities has made the transition from state vocational rehabilitation agency support.

(v) *Transitional employment* means a series of temporary job placements in competitive work in an integrated work setting with ongoing support services for individuals with the most severe disabilities due to mental illness. In transitional employment, the provision of ongoing support services must include continuing sequential job placements until job permanency is achieved.

(d) *Ongoing support services* means services that are:

(i) Needed to support and maintain an individual with the most severe disabilities in supported employment

- (ii) Based on a determination by the designated state unit of the individual's needs as specified in an individualized written rehabilitation program
- (iii) Furnished by the designated state unit from the time of job placement until transition to extended services, except as provided in §363.4(c) (3) and, following transition, by one or more extended services providers throughout the individual's term of employment in a particular job placement or multiple placements if those placements are being provided under a program of transitional employment. Ongoing support services must include, at a minimum, twice-monthly monitoring at the work site of each individual in supported employment to assess employment stability, unless under special circumstances; especially at the request of the individual, the individualized written rehabilitation program provides for off-site monitoring and, based upon that assessment, the coordination or provision of specific services at or away from the work site that are needed to maintain employment stability. If off-site monitoring is determined to be appropriate, it must, at a minimum, consist of two meetings with the individual and one contact with the employer each month. Ongoing support services consist of:
 - (A) Any particularized assessment needed to supplement the comprehensive assessment of rehabilitation needs
 - (B) The provision of skilled job trainers who accompany the individual for intensive job skill training at the work site
 - (C) Job development and placement
 - (D) Social skills training
 - (E) Regular observation or supervision of the individual
 - (F) Follow-up services such as regular contact with the employers, the

individuals, the parents, family members, guardians, advocates or authorized representatives of the individuals, and other suitable professional and informed advisors, in order to reinforce and stabilize the job placement

- (G) Facilitation of natural supports at the work site
- (H) Any other service identified in the scope of rehabilitation services described in 34 CFR part 361
- (I) Any service similar to the foregoing services

(Authority: 29 U.S.C. 706(18), 711(c), and 795j)

[59 FR 8331, Feb. 18, 1993, as amended at 62 FR 6363, Feb. 11, 1997]

Future Directions

Today, with the right type, level, and intensity of support, more and more individuals with intellectual disabilities are living and working in their communities (Wehman 2006; Wehman et al. 2003). Since its inception, supported employment has assisted individuals with significant disabilities with achieving positive employment outcomes (Wehman et al. 2006; Wehman et al. 1998). However, challenges remain for those who want to work. These individuals lack access to the support needed to gain and maintain work in their communities due to the slow conversion of day programs, slow expansion of program capacity among day programs that now offer integrated options (i.e., supported employment), no or limited individualized supported employment service options in such settings in favor of group models, and a lack of consumer choice and self-determination to help ensure meaningful employment outcomes. In addition, greater attention needs to be paid to employers. It is necessary to further investigate their perceptions, as well as examine more ways to motivate them to hire a person with a significant disability, such as customizing a job.

Sweden and Autism

Christopher Gillberg and Eva Nordin-Olsson
Department of Child and Adolescent Psychiatry,
Gillberg Neuropsychiatry Centre, University of
Gothenburg, Gothenburg, Sweden

Historical Background

Knowledge about autism in Sweden was very limited until the mid-late 1970s. The predominant view, based on no evidence, was that autism was caused by poor parenting. This view has been difficult to root out and has led to enormous suffering and unwarranted interventions well into the twenty-first century.

Anna-Lisa Annell, professor of child and adolescent psychiatry in Uppsala, had shown interest already in the 1950s in what was at the time referred to as childhood psychosis and its possible links with brain damage, as documented in her thesis on pertussis, possible anoxia attacks, and behavior problems in children.

In the 1960s child psychiatrist Karl Grunewald, later in life head of the Swedish National Board of Health and Welfare, started a campaign/lobbying with a view to improving the situation for young

and older people with intellectual disability. For a long time he was the driving force in the process of shutting down the big institutions for the “mentally retarded” (of whom many had undiagnosed autism). In 1968, the Swedish parliament passed the first law specifically stating the need for support and schooling for individuals with intellectual disability. This law (Omsorgslagen) was updated in 1986, and autism (“childhood psychosis”) was mentioned for the first time in Swedish legislation as a diagnosis that would *translate* support and schooling for affected individuals. This was followed by the 1993 Act concerning Support and Services for Persons with Certain Functional Impairments (LSS) in which *ten different rights* (including the right to a personal assistant) were specified and guaranteed for individuals with intellectual disability, autism and autistic-like conditions, traumatic brain injury with cognitive impairment, and other individuals with major physical or mental impairments in need of major support measures (Table 1). The aims and overall objectives of this development were to guarantee that people with severe disabilities would have as high a quality of life as possible, and that services and support due to lifelong disabilities would be free of charge and not cause extra costs to the individual. The Swedish Education Act updated in 2010 also specifies the right for all individuals – including those with disabilities – to get the best possible educational support so that they might achieve their full potential.

In parallel with Grunewald, Bengt Hagberg, Olle Hansson, and Karl-Gustaf Stukat, professors of Pediatrics and of Special Education in Gothenburg started a large population study of so-called Minimal Brain Dysfunction (MBD). The senior author of this chapter was one of the members of the clinical research team. He was also in charge of the medical services to a group home for children with “psychosis,” and later for all medical services to people with intellectual disability in and around Gothenburg. In planning the MBD study, he had read up about autism and childhood schizophrenia. He read Lorna Wing’s book *Autistic Children* from 1964 and also Hans Asperger’s 1944 paper on autistic psychopathy (later referred to as Asperger syndrome). The concepts of autism

(Mildred Creak’s “version,” Lorna Wing’s triad of social impairments and autistic psychopathy) were used in the MBD study and laid the groundwork for the Gothenburg autism studies, with the first publication on “Maternal age in infantile autism” appearing in 1980 and on “comorbidity” in 1983. From then on, the Gothenburg autism team led the development of research (and also to an extent clinical services) into autism and related disorders in Sweden. In the early 1980s, the only other center in which research and services for autism were developing was in Umeå, where professor Michael Bohman and his team did groundbreaking work around “childhood psychosis.” Psychologist Lena Andersson was one of the first to recognize the high rate of autism in immigrants. She collaborated with the Gothenburg autism group in several different projects (including the Nordic Twin Study of Autism and The Early Diagnosis “Rebecka” Project in the 1980s). For many years she was the secretary of the Autism Society and a key person (together with the chairmen/women of the society) in the spreading of autism knowledge across the country.

The National Autism Society – variously labeled Association for Psychotic Children, Association for Autism and since 2010 Autism and Asperger Syndrome Association – since its inception in 1973 (first chair Gunilla Dahlin, mother of a girl who later was diagnosed with Rett syndrome), has played an increasingly important role in assuring the development of services for individuals with autism in Sweden. In the early 1980s the association had 1000 members, many of whom were professionals working together with a few “powerhouse” parents of affected children. Twenty-five years later there are now 16,000 members, and the association is a strong “agency” with considerable clout vis-a-vis legislators, politicians, and administrators. The second author of this chapter was the chairman for 16 years (up until 2015), during which many of the very positive changes as regards assessment routines and interventions occurred. The society has been instrumental in delivering education (including e-learning) for parents, affected individuals, and professionals.

Legal Issues, Mandates for Service

The LSS-act from 1994 (see above) which guarantees a large number of different rights for people with a diagnosis of autism and autistic-like conditions (see Table 1) has gradually come to be interpreted much more narrowly than was intended by the legislators so that even with an unequivocal diagnosis of autism, individuals affected (or their parents) can no longer be sure that they will get what they need. It is assumed that one of the reasons for the more restrictive interpretation of the “circle of people” that is considered to have lawful right to the services detailed in the LSS-act is the enormous increase in the number of autism diagnoses made in some parts of Sweden (notably Stockholm) over the past 15 years. There is almost definitely “overdiagnosis” of autism in some areas of the country (Arvidsson et al. 2017). When the act was passed, it was assumed that the rate of autism was under half a percent. In Stockholm in 2011 almost 2.5% of 13–17-year-olds had been registered with a diagnosis of autism (Idring et al. 2015). Fewer and fewer symptoms seem to be needed for a clinical diagnosis (Arvidsson et al. 2017). This situation has led to skepticism on the part of those who assign/agree to services under the LSS-act, who argue that mild cases should not be able to avail themselves of equally comprehensive services (including personal assistants) as should those with very severe problems. At the

Sweden and Autism, Table 1 Act concerning Support and Services to Persons with Certain Functional Impairments. The ten rights

1	Advice and other personal support
2	Personal assistance
3	Companion service
4	Contact person
5	Relief service
6	Short-term stays away from home
7	Short-term care for school children over 12
8	Living in family homes or housing with special services for children and young people
9	Housing with special services for adults or other specially adapted housing for adults
10	Daily activities

same time, even though, by and large, awareness about autism has increased greatly over the past two decades, in-depth knowledge, particularly in schools and social services, has remained scarce.

Overview of Current Treatments and Centers

There are now relatively well-functioning child and adolescent autism assessment and diagnostic teams in many Swedish counties (although certainly not in all), usually within child and adolescent mental health services. In many ways, this has contributed to the development of better services in terms of educational and behavioral interventions, particularly for young children with autism. However, it has also, in some places, led to an overfocus on autism as the only problem in children with the disorder. As has been demonstrated by the Gothenburg research group since the beginning of the 1980s, clinically relevant autism usually does not come “alone.” Instead, comorbidities (e.g., intellectual disability, language disorder, motor coordination problems, ADHD, tics, hearing and visual deficits, epilepsy, etc.) are the rule. These associated problems are often highly treatable, but in recent years, the diagnosis of autism has overshadowed them to the extent that they are not always properly diagnosed or treated. In other places, autism-specific knowledge has been watered down to the extent that there is little or no understanding of the special needs for individuals with a diagnosis of autism. By and large though, the situation for young children with autism in Sweden is much better now than 40 years ago, even though the separation of assessment and intervention services remains a problem with child psychiatry usually providing the assessment and habilitation services (without being involved in assessment) the intervention. Teenagers and adults with autism are often misunderstood and misdiagnosed, and “autism-specific” competence in schools and social services is rare. In adult psychiatry there is growing interest in and awareness of autism, but, again, in-depth knowledge is lacking in many places, leading to missed diagnoses, and,

sometimes, unwarranted treatments (such as with atypical neuroleptics for what is considered “psychosis” or “personality disorder” rather than social communication deficits and behavioral peculiarities that are typical of autism spectrum disorders). In Sweden there has, rightly, been a lot of emphasis on early diagnosis and early intervention in autism. The need for very long-term follow-up (indeed sometimes life-long) has often been ignored, and a focus on transition and adulthood is much talked about but not “breaking through.” Unfortunately, services for adults with autism and related disorders are still nowhere near as well developed as are those for younger people.

Overview of Research Directions

The Gothenburg group has been leading the international field in epidemiological autism research for many years. Together with Lorna Wing, who gradually became a close collaborator, the group was first to draw attention to the much higher than previously reported rate of autism, claiming already in the 1980s that the “true” prevalence of the disorder was around 1% of the general population. The group has since shown that the rate of the autism phenotype in the population appears to be very stable over the years (and remaining around 1%), but that the clinical diagnosis of autism is made more and more often, sometimes in cases with neurodevelopmental problems that do not meet the diagnostic criteria for autism. The Swedish epidemiologically based studies of autism (and Asperger syndrome) are unique in an international perspective. Very little in-depth study of epidemiological cohorts is published by other groups.

Autism research in Sweden is holistic and ranges from groundbreaking genetic research (in collaboration with a French group led by professor Thomas Bourgeron), epigenetics (including pioneering work on vitamin D deficiency in autism in Somali immigrants and in pregnant mothers of children who later get a diagnosis of autism), clinical presentation (which has led to the concept of Autism Plus, i.e., that clinically impairing autism is usually associated with

significant comorbidity), early symptoms (including work that suggests that motor-perceptual problems may be the first to signal autism, and there might be a slightly different phenotype in girls), longitudinal population-based studies from childhood into late middle age of low- and high-functioning individuals, twin studies, various intervention RCTs, and to neurochemical, neurophysiological, imaging, and neuropsychological studies. The ultimate goal is to get at “the bigger picture in autism” at the same time as understanding the molecular basis and brain functioning.

Social Policy and Training

Many advances have been achieved in the past 40 years. On-going training of providers (doctors, psychologists, nurses, teachers, and others) remains a top priority for the autism center in Gothenburg and in the past several years in other places in Sweden, including Stockholm. Efforts have been made for the last 30 years, particularly by the National Autism Association, to develop and implement curricula to enhance effective teaching methods and alternative communication in schools, classrooms, and everyday-life situations, often inspired by the TEACCH “philosophy.” The Autism Society has also been promoting the “low-arousal” approach advocated by Bo Hejlskov Elvén and Ross Greene. In the past 15 years, ABA-approaches and early intensive programs (along the lines of Denver Early Start program) have come to the forefront and been strongly advocated by a small group of influential specialists. However, recent Swedish research has not supported the superiority of intensive versus nonintensive interventions in naturalistic settings, and there is now, perhaps, a return to a more eclectic and individually designed approach addressing all the specific needs of each child treatments and other interventions, including education and social support, in each child.

Establishing the evidence base of interventions should be a top priority in the next several years. Also, a stronger focus needs to be directed at adults and old people with autism, who still do not get the attention that they are in need of in our country.

Symbol Use

Anne Snow
Child Study Center, Autism Program, Yale
University, New Haven, CT, USA

Definition

The term “symbol use” is often used to describe the deficits in communication that characterize individuals with autism spectrum disorders (ASD; Marans et al. 2005). The capacity for symbol use refers to an individual’s ability to use one thing to represent another. Symbolic behavior is evident in verbal as well as nonverbal communication through the use of

words as labels, and the use of gestures. An additional domain of symbol use relevant to ASD is that of symbolic play, in which non-present elements are represented by objects, gestures, or language during the play (Rogers et al. 2005).

A deficit in symbol use is a core social communication deficit that distinguishes young children with ASD (Wetherby and Woods 2008). At a prelinguistic level, this is seen in a deficit of symbolic behavior. This includes gestures, pretend or imaginative play, and the ability to imitate others (Paul and Sutherland 2005). In higher-functioning individuals, the deficit in the capacity for symbol use is seen in difficulties with using language in a flexible manner, such as responding to language that includes words with multiple meanings, non-literal language, and irony (Marans et al. 2005). An additional area of social communication that might be affected includes symbolic conventions, such as rules of politeness.

Symbolic Behavior

Erin Rotheram-Fuller¹ and Mina Kim²

¹School Psychology, Department of Psychological Studies in Education, College of Education Temple University, Philadelphia, PA, USA

²College of Education Temple University, Philadelphia, PA, USA

Definition

Symbolic behavior is an encoding process in which items or actions are used to represent something different (Huttenlocher and Higgins 1978). Engaging in symbolic behavior elicits a network of experiences that is a result of the history of actions that are associated with that particular symbol (Volkmar et al. 2005). The development of a symbol is related to adaptation, in which somatosensory experiences and perceptually guided actions are integrated, and turns the symbol into a substitute for the action (Volkmar et al. 2005). Imitation is also believed to be a prerequisite for the development of symbolic behavior (Volkmar et al.). Language is the most important type of symbolic behavior; it is also evident in storytelling, play and games, and gestures (Greenberg 1971; Jones 1996).

Symbolic behavior functions to create and maintain a common meaning that is shared socially. It validates norms for behaviors and allows individuals to engage in behaviors that connect them together (Harris and Nelson 2007; Jones 1996). Symbolic behavior can also create and maintain social interactions. The use of symbols is reliant upon the expected response from others (Volkmar et al. 2005). It is the expectation of shared meaning that both initiates and perpetuates an interaction when one seeks to engage with others and interpret the symbol to represent the same meaning.

Early symbolic behavior can be seen in pretend play and imitation, where an object or person is

used to represent another (Volkmar et al. 2005). It is concurrent with the development of language, and “marks the existence of a vivid and active internal world for the young child” (Berg and Sternberg 1985, p. 68). Symbolic play usually develops around 2–3 years, although the use of symbolic gestures as a function of communication has been observed in children as young as 11 months of age (Acredolo and Goodwyn 1988). A child’s current level of symbolic behavior can be determined by examining the highest level of play that is spontaneously exhibited by the child (Paul 2007), and is closely related to the child’s understanding of a symbolic system, such as language (Christie 1991).

Historical Background

Children with ASD have difficulties demonstrating symbolic behavior (Baron-Cohen 1987; Charman and Baron-Cohen 1997; Libby et al. 1998; Stahmer 1995; Wing et al. 1977). The diagnostic criteria for autism include a deficit in symbolic play, particularly in pretend and imitative play, observed before the age of 3 years (American Psychiatric Association [APA] 2000). Given the importance of symbolic behavior in the development of linguistic, social, and cognitive skills, several studies have been conducted to both examine the symbolic play skills of children with ASD and develop interventions to improve those skills.

In early studies of symbolic play among children with ASD (Hammes and Langdell 1981; Wing et al. 1977), they were found, overall, to have a lack of spontaneous symbolic play. Those children with ASD who did exhibit symbolic play also had more repetitive and stereotyped play (Wing et al.). Although children with ASD were able to imitate video-modeled play acts similarly to children with intellectual disability, they had significantly fewer spontaneous symbolic acts (Hammes and Langdell 1981). A common theme in the symbolic play literature appears to be that scaffolding (prompting) improves the ability of children with ASD to engage in symbolic play; however, this type of play is still lacking in their

spontaneous play (Blanc et al. 2000, 2005; Lewis and Boucher 1988; Sigman and Ungerer 1984; Volkmar et al. 2005).

There are several areas of symbolic play which can be affected for children with ASD. In general, children with ASD do not spontaneously exhibit symbolic play as frequently as other children (Blanc et al. 2005; Hammes and Langdell 1981; Wing et al. 1977). There is also a lower complexity and variety in the type of symbolic sequences used by children with ASD (Blanc et al. 2005; Wing et al. 1977). It has been hypothesized that these deficits may be a result of dysregulation (Blanc et al. 2005), difficulty with meta-representation (Baron-Cohen 1987; Volkmar et al. 2005), or a lack of generativity of ideas (Lewis and Boucher 1988). Limited symbolic play abilities may also be a result of a lack of social opportunities or more general symbolic thought and language difficulties (Volkmar et al. 2005).

Current Knowledge

Children with ASD have been observed to demonstrate less symbolic behavior compared to their typical peers or peers with other disabilities (Baron-Cohen 1987; Charman and Baron-Cohen 1997; Libby et al. 1998; Stahmer 1995; Volkmar et al. 2005; Wing et al. 1977). Research suggests that children with ASD use less complex nonverbal behavior to communicate, and they demonstrate a disordered pattern that suggests the misuse and misunderstanding of nonverbal communication (APA 2000). Children with ASD are able to imitate symbolic behavior but seem to have more difficulty producing their own symbolic actions (Blanc et al. 2005; Hammes and Langdell 1981; Wing et al. 1977). Additionally, deficits in functional and pretend play have been observed, even after they have been modeled by others (Chawarska et al. 2008).

Children with ASD also demonstrate a qualitatively different symbolic play than typically developing children or those with other disabilities, with more object substitutions, fewer attributions of false properties, and no references to

absent objects (Blanc et al. 2000, 2005; Lewis and Boucher 1988; Sigman and Ungerer 1984; Volkmar et al. 2005). Significant differences in the types of symbolic behaviors used to communicate (i.e., gestures, eye gaze, requesting, and commenting) have also been observed (Stone et al. 1997). It has also been found that children with ASD use unconventional gestures and do not use gestures spontaneously (Chawarska et al. 2008). Overall, children with ASD seem to communicate for different reasons, using different types of symbolic and nonverbal behaviors to communicate, and these differences can be detected as early as 2–3 years of age (Stone et al. 1997).

Children with ASD who are able to demonstrate symbolic play behaviors have significantly higher verbal and nonverbal IQs compared to those who do not (Baron-Cohen 1987). However, even when children with ASD are able to demonstrate symbolic play skills before starting school, they still show poorer play abilities relative to typical peers (McDonough et al. 1997). Various studies have suggested that symbolic play improves after modeling and that children with ASD are able to engage in symbolic play when the symbol is suggested by another person (Blanc et al. 2000, 2005; Lewis and Boucher 1988; Sigman and Ungerer 1984; Volkmar et al. 2005). However, during spontaneous play conditions, children with ASD demonstrate fewer different play behaviors, as well as less functional and sensorimotor play (Volkmar et al.).

Early studies suggested that a relationship existed between language development and symbolic play skills in children with autism (Sigman and Ungerer 1984); however, more recent studies have reported the absence of a relationship between functional and symbolic play and verbal language (Blanc et al. 2005; Charman and Baron-Cohen 1997; Volkmar et al. 2005). Linguistic abilities can remain intact, while symbolic behaviors continue to be a challenge for children with ASD (Blanc et al. 2005). There may be distinct communication difficulties associated with autism (e.g., pragmatic joint attention or unusual lexical patterns) that specifically underlie problems with symbolic behavior (Miller 2007).

Symbolic behavior is commonly measured using the Communication and Symbolic Behavior Scales (CSBS), developed by Wetherby and Prizant (1998). The CSBS consists of a caregiver questionnaire and direct assessment and examines the communicative, social, and symbolic functioning of children up to 6 years old with communication skills between 6 and 24 months old. The CSBS is used to identify at-risk children, guide interventions, and establish profiles that can be monitored over time (Volkmar and Marans 1999).

In addition, the CSBS Developmental Profile (CSBS-DP) is another standardized tool developed by Wetherby and Prizant (Wetherby et al. 2002) to evaluate the communication and symbolic behavior of children from 6 to 24 months old. Based on the CSBS, the CSBS-DP consists of a behavior sample, which is a face-to-face evaluation of a child's interaction with a parent and clinician. Three categories of skills are assessed: social, speech, and symbolic scales. The CSBS-DP has been found to be valuable for predicting later language based on the child's social-communication skills, and positive predictive values for communication delays above 70% for children of ages 9–24 months (Barton et al. 2010; Wetherby 2006). A copy of the caregiver questionnaire used for the CSBS-DP can be found online: <http://www.brookespublishing.com/tools/csbsdp/caregiverquestionnaire.pdf>.

Another method used to evaluate symbolic play in nonverbal children is the Carpenter's Play Scale (Carpenter 1987), which infers a child's symbolic play during four 8-min play scenes with a parent. Using appropriate prompt materials (e.g., tea cups), the actions of the nonverbal child are interpreted to evaluate the presence of symbolic play with those materials (e.g., pretending to drink from the cup). Parents are asked to follow the child's lead throughout the sessions. Similarly, McCune (1995) developed a hierarchical scale on which to rate spontaneous symbolic play behaviors during interactive sessions with a familiar adult using standardized items (e.g., bed and covers, toy food, cars). Both methods use interactional observations to determine the presence of symbolic play behaviors, and have relatively strong validity and reliability.

Another assessment of play skills in children with autism has been adapted from those used with typically developing children. The Structured Play Assessment (SPA; Ungerer and Sigman 1981) is a developmental play assessment that uses several standardized toy sets that are placed in front of the child sequentially to examine how the child plays with the toys. Children are presented with each toy set for approximately 3–4 min, for a total of a 15–20-min videotaped observation. Several features of play are coded, such as the number of different play acts and the diversity of play, which can ultimately provide a developmental profile of the child's play activity level (Kasari et al. 2006).

Future Directions

Given the difficulties of children with ASD to master symbolic play skills, it seems critical to continue focusing both assessment and intervention studies in this area. It remains unclear exactly why children with ASD struggle with symbolic behavior skills, although several hypotheses have been proposed. While some studies suggest that children with ASD lack the ability to manipulate symbols purposefully and meaningfully (Hammes and Langdell 1981), other studies propose dysregulation as a more fundamental challenge underlying symbolic play skills (Blanc et al. 2005). Especially given the mixed nature of the literature on the relationship between communication and language with symbolic play skills, additional studies are needed to better evaluate this area. More information is clearly needed to better identify the multiple underlying issues relevant to symbolic behavior that are specifically affecting children with ASD.

In addition, to identify the underlying causes for difficulties in symbolic play, there are several associated areas that relate to symbolic behavior, which remain to be explored by the current literature. For example, the relationship between symbolic behavior and social interest, social orientation, imitation, developmental skills, etc., among children with ASD has not been fully examined (Volkmar et al. 2005). Both child-

specific (e.g., neuropsychological) and environment-specific (e.g., exposure to symbolic play practice) areas should be explored (Volkmar et al.).

Better identification of symbolic behavior difficulties can also aid in the early diagnosis of children with ASD. Given that difficulties in this area are a core feature of ASD (APA 2000), there is good reason to use this skill as an early marker of the disorder (Blanc et al. 2005). There is also a great need for early intervention strategies to address this core deficit. Recent studies targeting symbolic play among children with ASD have been successful in improving this skill (Kasari et al. 2006; Stahmer 1995; Thorp et al. 1995); however, more studies are needed to replicate and expand these findings. Naturalistic behavioral procedures, such as Pivotal Response Training, appear to be promising approaches to teaching symbolic play skills to children with ASD (Kasari et al. 2006; Stahmer 1995; Thorp et al. 1995). Given that there are now models of interventions to follow in teaching symbolic play skills, those methods should be examined across populations of children with ASD to identify for whom the methods work best.

Symbolic Play

Brooke Ingersoll and Sara Jelinek
Department of Psychology, Michigan State
University, East Lansing, MI, USA

Definition

Play emerges in a specific developmental sequence (Belsky and Most 1981). First, children handle toys in manipulative ways by touching, mouthing, and smelling. Functional play or appropriate play with objects develops at approximately 14 months of age in typically developing children. At about 24 months of age, symbolic play emerges. Symbolic play is behavior that is simulative or nonliteral (Fein 1981) and involves acting as if something is the case when in reality it is not (Leslie 1987). Definitions of symbolic play used in the majority of research with children with autism typically involve the following three symbolic forms of pretense (Leslie 1987): object substitution, in which one object is used to represent another (e.g., using a hairbrush as a telephone); attribution of absent/false properties (e.g., pretending that a stove top is hot when it is not); and imaginary objects present (e.g., pouring tea from an imaginary tea pot). A number of terms have been used interchangeably with symbolic play, including “pretend, fantasy, imagination, and nonrepresentational play” (Jarrold et al. 1993). These terms, however, do not have consistent definitions and may include actions with objects, such as pretending to feed one’s self or a doll with a spoon, that do not show true evidence of symbol use since the child may actually perceive the toys as smaller versions of real objects (Baron-Cohen 1987).

Historical Background

Children with autism exhibit significant deficits in the development of symbolic play (Jarrold et al. 1993). Indeed, a “lack of varied, spontaneous, make-believe play” is a diagnostic criterion for

autism in the DSM-IV (American Psychiatric Association 2000). The view that children with autism have impaired symbolic play was first noted by Kanner in 1943 and has subsequently been supported by a number of studies that have compared the ability of children with autism to engage in symbolic play with other groups of children (e.g., typically developing, language delayed, intellectually disabled), matched in a variety of ways (e.g., chronological age, mental age, language age). Symbolic play has been traditionally measured by observing the child interact with a standard set of toys and recording the number of play actions produced of various types (e.g., functional, symbolic). A commonly used play measure is the Lowe and Costello Symbolic Play Test (Lowe and Costello 1976). Children are presented with four sets of toys, and their spontaneous engagement with the toy is observed. If the child does not spontaneously engage with the toy set, then they are provided with a prompt such as “what can you do with these” (Stanley and Konstantareas 2007). The child’s score from this test is used to determine their play age.

These studies have typically demonstrated that children with autism are significantly less likely to spontaneously produce symbolic play acts than children without autism functioning at a similar developmental level (see Jarrold et al. 1993 for review). The ability to engage in symbolic play appears to be closely related to both nonverbal and verbal skills. For example, in Baron-Cohen’s (1987) study, children with autism who did engage in symbolic play had significantly higher nonverbal mental ages than those who did not. This finding supports a relationship between symbolic play and cognitive development. Further, Stanley and Konstantareas (2007) found that children with autism who exhibited greater cognitive impairment showed lower symbolic play skills, and higher expressive language abilities were associated with better symbolic play skills. However, symbolic play was not significantly related to social development.

Interestingly, although deficits in the spontaneous use of symbolic play have been consistently observed across studies, there is evidence that children with autism can produce symbolic play

acts in a structured, elicited setting. For example, Charman and Baron-Cohen (1993) found that children with autism were able to produce a similar number of object substitutions in response to a prompt as children with mental retardation matched on verbal mental age. However, Sigman and Ungerer (1984) found that although children with autism were able to produce some symbolic acts in response to a prompt, they still produced fewer acts than the control group. In general, studies have found that deficits in the spontaneous production of symbolic acts during play are more pronounced than the ability to produce symbolic acts in a structured situation; however, deficits in both of these abilities appear to be present, particularly in younger children with autism.

A number of theoretical accounts of autism have attempted to explain the deficit in symbolic play (see Jarrold et al. 1993 for review). The *metarepresentational* or *theory of mind* hypothesis holds that children with autism have a specific deficit (Leslie 1987) or delay (Baron-Cohen 1989) in the ability to form metarepresentations or symbolic second-order representations. It is this underlying cognitive deficit that produces the observed lack of symbolic play in children with autism. Several researchers have suggested that an underlying social deficit, either in the ability to affectively connect with others (Hobson 1990) or in intersubjectivity (Rogers and Pennington 1991), disrupts early emotion sharing and attunement between the infant and the parent and leads to later emerging deficits in symbolic play via its impact on the child's ability to recognize others as having differing views of the same situation. The *executive functioning* or *generativity* hypothesis (Harris 1993; Jarrold et al. 1996) suggests that executive functioning problems interfere with the child's ability to generate internal representations or schemas in the absence of prompts or cues. Thus, their spontaneous play remains highly repetitive and stereotyped. Although symbolic play deficits are one of the defining features of the disorder, there is evidence that children with autism exhibit deficits in functional play as well (Jarrold et al. 1993), which has been used to support the view that symbolic play deficits may

be the result of a more general deficit in executive functioning.

Current Knowledge

A number of more recent studies on the symbolic play skills in children with autism have clarified a number of questions regarding the scope and underlying causes of symbolic play deficits. One question is whether symbolic play deficits are due to difficulty in understanding the underlying symbolic representation (competence) or whether they are due to difficulty in generating play ideas (performance). Research with young (Rutherford et al. 2007) as well as older (Bigham 2010) children with autism has suggested that children with autism have difficulty both with the spontaneous use as well as the prompted use of symbolic actions, suggesting a difficulty with competence rather than performance. However, there is also evidence that children with autism's spontaneous symbolic play is more impaired than their prompted symbolic play, suggesting that the ability to generate play ideas may also be impaired.

Another issue in the field is whether play deficits in autism are specific to symbolic actions or are more general, involving functional actions as well. To date, the field has been mixed. Several studies, particularly those involving young children with autism, have suggested that play deficits extend to functional actions as well (Rutherford and Rogers 2003), whereas other studies have found deficits only on symbolic play tasks (Baron-Cohen 1987; Libby et al. 1997). One recent longitudinal study found that children with autism exhibited impairments in both functional and symbolic play when compared to children with typical development or developmental delay in the early preschool period. However, 1 year later, deficits in functional play were no longer present; yet symbolic play skills remained impaired (Rutherford et al. 2007). Thus, there appears to be an improvement in functional play with time, but not in symbolic play.

Several recent studies have attempted to directly test theories proposed to explain symbolic play deficits in children with autism. In one study,

longitudinal predictors of symbolic play were examined in preschoolers with autism, developmental delay, and typical development. Predictors included a spatial reversal task (a task thought to tap executive functions in preschoolers), joint attention (thought to be a precursor to meta-representation or theory of mind), and imitation. Joint attention skills were predictive of gains in symbolic play over time, whereas spatial reversal and imitation performance were not. In a second study with older children with autism, intellectual disability, and typical development, performance on a false belief task (an index of theory of mind ability) was concurrently associated with understanding of symbolic play acts, but not response inhibition (an aspect of executive function). Thus, current work is more supportive of a meta-representation explanation for symbolic play deficits.

Due to the prevalence and persistence of symbolic play deficits in children with autism, a number of intervention approaches have been used to teach symbolic play skills to children with autism (see Lang et al. 2009 for review). For example, Kasari, Freeman and Paparella (2006) used a randomized controlled trial to evaluate a symbolic play intervention that used structured and naturalistic teaching strategies in young children with autism. Children were randomly assigned to receive symbolic play training, joint attention training, or a control group. After 6 weeks, children in the symbolic play training group showed a significantly greater number of different, novel, child-initiated symbolic play acts and higher play level than children in the other two groups. Finally, the researchers found the children were able to generalize their skills from the individualized treatment with a therapist to playing with their caregiver (Kasari et al. 2006). In a follow-up study (Kasari et al. 2008), children in the symbolic play training group (and joint attention training group) made greater gains in language on standardized measures than the children in the control group 1 year later, suggesting that improving symbolic play skills can lead to improvements in language skills. Interestingly, although symbolic play and expressive language ability appear to be closely related in children with

autism (Stanley and Konstantareas 2007), training in language skills did not produce changes in use of symbolic play acts (Stahmer 1995), indicating that symbolic play skills may need to be directly targeted.

Future Directions

The vast majority of research on symbolic play in children with autism has examined these skills at a single time point. Future research is needed that can examine changes in symbolic play over time. In particular, it is important to examine both predictors of gains in symbolic play skills as well as outcomes of gains in symbolic play. Further research that can examine effective methods for improving symbolic play skills in children with autism is needed.

Symbolic Thought

Erin Rotheram-Fuller

School Psychology, Department of Psychological Studies in Education, College of Education
Temple University, Philadelphia, PA, USA

Synonyms

[Intuitive thought](#)

Definition

Symbolic thought refers to the use of symbols (e.g., words and images) and mental representations of objects or events to represent the world (Hockenbury and Hockenbury 2002; Rathus 2007). Symbolic thought is one of the major developmental outcomes of language acquisition, and the ability to understand and use symbols allows children to engage in intellectual and social activities that are unique to humans (Carlson and Zelazo 2009; Karpov 2005).

There are two constructs of symbolic thought: mediation and intentionality. In mediation, a symbol is substituted for a real stimulus, and behavior can be controlled by the symbol rather than the stimulus. Intentionality refers to the awareness of the relationship between the symbol and the stimulus (Karpov 2005).

Symbolic thought gradually develops throughout infancy and early childhood and is evident in a child's use of imagination while playing (Carlson and Zelazo 2009; Hockenbury and Hockenbury 2002). The capacity for symbolic thought allows a child to begin abstract thinking and act

independently of what he or she sees and to begin abstract thinking (Karpov 2005). Its development is related to the development of self-reflection and social interaction (Carlson and Zelazo 2009). It is a precursor to sociodramatic play, such as role-playing (Karpov 2005). Children with an immature understanding of symbols may not understand the relationship between symbols and the objects they represent (Hockenbury and Hockenbury 2002).

synapses, chemical and electrical, differentiated by the method by which these action potentials travel between neurons. In chemical synapses, neurotransmitters are required to pass an action potential across the synaptic cleft, the space between the axon terminal and the dendrite. In electrical synapses, two neurons are physically connected via gap junctions allowing for action potential transmission.

Synaptic Proteins

John D. Murdoch and Michael F. Walker
Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Structure

The synapse is a highly specialized junction between two neurons, consisting of a presynaptic cell, a postsynaptic cell, and a space between the membranes of the two cells. There are two kinds of synapses, chemical (neurotransmitter-driven) and electrical, both occurring between neurons; to date, the synaptic proteins implicated in autism are involved in chemical synapses. In a chemical synapse, the presynaptic neuron is responsible for creating chemical neurotransmitters in small membrane-sealed droplets called vesicles, storing these in the presynaptic axon terminal (the part of the presynaptic neuron abutting the synaptic cleft) and releasing them into the synaptic cleft to bind to receptors on the membrane of the postsynaptic

Synapses

Danielle Bolling
Yale Child Study Center, New Haven, CT, USA

Definition

A synapse is the area forming the junction between two neurons where an action potential passes from the axon terminal of one neuron to the dendrite of another. There are two types of

density, the specialized portion of the postsynaptic neuron on the synaptic cleft directly opposite the presynaptic axon terminal (Dubin 2002; Peça et al. 2011; Purves et al. 2001; Sherwood 2010). Voltage-modulated calcium ion channels on the presynaptic terminal allow an influx of calcium ions which prompts the stored vesicles to fuse with the cell membrane and release their neurotransmitter contents into the cleft (Lodish et al. 2000; Purves et al. 2001). Synapses can be excitatory or inhibitory, depending on whether they involve the release of an excitatory neurotransmitter or an inhibitory neurotransmitter. Binding of excitatory neurotransmitters to their specific receptors on the postsynaptic density causes ion channels linked to the receptors to open, allowing an influx of sodium ions to enter the cell, depolarizing it and increasing the likelihood that it will fire a signal, or action potential, across its synapse to the next neuron in the pathway, and so on. The binding of inhibitory neurotransmitters to their specific receptors on the postsynaptic density, conversely, results in the channels opening to allow influx of chloride ions or efflux of potassium ions, resulting in increasing polarization of the cell and reducing the probability that it will fire an action potential and transmit a signal to the following neuron (Alberts et al. 2002; Lodish et al. 2000; Sherwood 2010). Synaptic proteins play roles in all of this, from synaptic formation and development to synapse maintenance and signal transmission, and are responsible for the structure of both the presynaptic terminal and the postsynaptic density, as well as structural connections spanning the synaptic cleft.

Function

Synapses are essential to neural function and thus all brain activity. By relaying signals from one neuron to another and modulating the strength of the relayed signal (keeping it the same, attenuating it, or amplifying it), they allow for highly complex signals and “messages” between neurons and over long distances (neurologically speaking, i.e., along connections millions of cells long).

In a structure as specialized and involved as the synapse, understandably, synaptic proteins will vary widely in form and function. Some of the proteins are involved in large-scale structural alignment of the synapse, connecting with each other across the cleft anchoring the synapse together, as well as relaying the received signal on the postsynaptic side; these include CASK, neuexins, ERC, Piccolo, Bassoon, and catenins (presynaptic) (Waites and Garner 2011; Ziv and Garner 2004), and various neurotransmitter receptors, neuroligins, PSD95, SAP97, SAPAP, and SHANK genes (postsynaptic). Some, such as cadherins, which interact with each other across the synaptic cleft, and catenins, which interact with the cadherins inside the cell, occur on both sides of the synapse (Peça et al. 2011; Waites and Garner 2011; Ziv and Garner 2004). Others are involved in vesicle trafficking and secretion; these include syntaxin, Snap25, Rim, Rab3a, Munc13, and Munc18 (Ziv and Garner 2004).

Pathophysiology

Given the vital role synapses play in neural function, it is easy to understand how synaptic dysfunction could result in neuropsychiatric conditions. In recent years, a growing number of synaptic proteins have been implicated in the pathogenesis of autism. Nearly all of those that have been associated with autism have been so in the context of rare, likely highly deleterious mutations that would severely disrupt the function of the protein in question. When mutations in synaptic proteins are reported in association with autism, typical implicated pathologies are problems in neuronal migration and connection, as well as abnormal dendritic spines (the protruding structure of which the postsynaptic density is the end) (Waites and Garner 2011). The interacting neuexins (presynaptic) and neuroligins (postsynaptic) neuexin-1 (NRXN1) and neuroligin 4 X-linked (NGLN4) have been implicated several times and have the strongest evidence for involvement in ASD. Mutations in neuroligin 3 have also been identified in patients with ASD, and a mouse model of one mutation

identified in an ASD family demonstrated changes in synaptic function. Downstream of neuroligins in the postsynaptic density are the SHANK genes, binding indirectly to the neuroligins (Südhof 2008). Mutations/deletions in SHANK3, as part of 22q13.3 deletion syndrome, make it one of the most convincing and replicable autism genes (see ► [“SHANK 3”](#) entry). More recently, SHANK2 has also emerged as an autism candidate (Berkel et al. 2010, 2012, reviewed in Penzes et al. 2011). Cadherins have also been recently implicated in autism, including through the finding of a significantly associated SNP mapping between the genes encoding CDH9 and CDH10 (Wang et al. 2009) in the first large-scale genome wide association study in ASD. As noted, this finding has yet to be independently replicated. These types of proteins interact with each other across the synaptic cleft and are the cytoplasmic binding partners of the catenins (Waites and Garner 2011; Ziv and Garner 2004).

The notion that ASD is, at least in part, a reflection of synaptic pathology is supported by the increased rates of autism spectrum disorders in fragile X syndrome and in tuberous sclerosis. The genes that cause these syndromes, namely, FMRP (fragile X mental retardation protein), TSC1 (tuberous sclerosis complex 1), and TSC 2 (tuberous sclerosis complex 2), are known to play important roles in synaptic function.

Further research into these synaptic proteins will result in a greater understanding of their precise roles in synaptic function, and thus clarify how they are involved in autism. This will in turn hopefully allow for better diagnostic methods and treatment options, informed by the presence or absence of causative mutations in specific synaptic genes.

Synaptic Pruning

Su Mei Lee

Child Neuroscience Lab, Yale Child Study Center, New Haven, CT, USA

Definition

Synaptic pruning is the process by which synaptic connections that are weak, usually as a result of

being underused, are eliminated. This process of eliminating weak connections allows the brain to process more frequently encountered and relevant information with greater efficiency. It is part of the developmental process and results in changes in cortical thickness over time.

Synaptogenesis

Danielle Bolling
Yale Child Study Center, New Haven,
CT, USA

Definition

Synaptogenesis is the formation of synapses between neurons. This process begins in gestation and continues throughout life. The greatest amount of synapse formation occurs early in life, during what is referred to as a “critical period” in development, during which sensitivity to developmental influences is heightened. Synaptogenesis in early development is coupled with synaptic pruning, the deletion of excess synapses.

Definition

Syntax is the set of rules and principles that govern the organization of words into sentences in any individual language. In typical development, adult-like syntax is acquired by age 5. In ASD, it has long been thought that syntax is relatively spared and usually on par with cognitive development. However, recent research suggests that a subgroup of speakers with ASD have syntactic deficits above and beyond their cognitive limitations that resemble the deficits seen in specific language disorders.

Synonyms

Empathizing-systemizing theory; Organizational prevention; Systemizing

Definition

Systems are a set of interacting or interrelated entities forming an integrated whole or larger,

more complex formation. Interventions are acts of intervening or coming between two or more things or acts that occur between two or more points in time. When combined, the terms systems and intervention describe actions that either purposefully or incidentally interfere with a larger organizational configuration. Systems intervention can occur at macro and micro levels. Systems approaches at the larger, macro level are organizational arrangements that enhance and diminish treatment effectiveness. Volkmar et al. (2005) describe systems as being a part of the environment and are found within six classifications, each with its own set of rules and regularities: technical, natural, abstract, social, motoric, and organizational. The interactivity of these six components, each working separately within its own unique parameters and then as a collective whole, coordinate to form a system. In developing systems intervention, consideration for the larger system and each interlocking component with surrounding parameters needs to be analyzed and evaluated for causal roles and relationships.

At the micro level, the concept of systems intervention applies to specific treatments, interventions, or evidence-based practices aimed at intervening by aligning with particular approaches and methodologies that focus on a systematic delivery of intervention following a standardized protocol. For example, the Picture Exchange Communication System (PECS) is a training protocol that is based on applied behavior analysis (ABA) techniques, whereby functional communication is systematically taught using prompting and reinforcement strategies that lead to independent communication. PECS also teaches discrimination of symbols and then sequencing to create simple sentences. In the most advanced phases, individuals are taught to comment and answer direct questions.

Further, with respect to systems and organizations represented within the individual with ASD, it is hypothesized that input-output systems are affected by the disability and the systemizing of information may be compromised given deficit areas involving communication, behavior, and social reciprocity.

Synonyms

[Standardized scores](#)

Definition

T scores (or T-scores) are an example of standardized scores, where the mean is equal to 50 and the standard deviation is equal to 10. They are a linear transformation of Z-scores, which have mean 0 and standard deviation 1; a T score can be obtained from a Z-score by the formula $T = 50 + 10Z$. T scores are convenient because scores below 0 and above 100 are virtually impossible; in fact, 99.7% of the time, a T score will lie between 20 and 80, because these limits are 3 standard deviations below and above the mean, respectively. The Mullen Scales of Early Learning is one example of an assessment that reports T scores.

Definition

A tact is a verbal action evoked by something in the environment and reinforced by an unspecified consequence (Skinner 1957). For example, if a child who sees a picture of a dog says “Doggy!” and the child’s parent then smiles and replies, “Wow! That *is* a dog,” the child’s statement (i.e., “Doggy!”) would be considered a tact. This term was introduced by B. F. Skinner and refers to a specific type of verbal act within an operant conditioning framework designed to analyze the functions of verbal behavior.

Tactile

Winifred Schultz-Krohn
Department of Occupational Therapy, San José State University, San José, CA, USA

Synonyms

[Touch](#)

Definition

Tactile or touch is a sensory experience that is first detected by receptors in the skin. These receptors then transmit the information into the spinal cord to be further processed. Tactile information is diverse and carried through different pathways in the spinal cord to provide the brain with specificity about the encounter of the skin with the environmental object that produced the touch. For example, tactile information may be used in a discriminatory manner to sort sizes of coins without the use of vision, or the tactile sensation may be protective in nature when an unexpected touch is encountered. The discriminative tactile sensation can be refined with training, as is seen when teaching a person to interpret Braille.

Tactile Defensiveness

Kristen M. Powers

Coordinator of Rehabilitative Services, Center for Children with Special Needs, Glastonbury, CT, USA

Synonyms

[Tactile sensitivity](#); [Touch sensitivity](#)

Definition

Individuals with autism spectrum disorders with tactile hypersensitivity have been commonly reported in the literature (Baranek et al. 1997). Individuals with tactile defensiveness may show reluctance to manipulate various textures and materials based on their texture or may exhibit an exaggerated or persistent response to unexpected touch occurrences and may even avoid situations in which these materials are presented or settings in which unexpected touch may occur. Additionally, these individuals may exhibit hypervigilance to the potential threat of unexpected touch occurrences. Individuals with tactile defensiveness may also restrict their food repertoire based on texture of the food itself. Participation in such activities of daily living as hair cutting, nail cutting, and toothbrushing may also be impacted by tactile defensiveness. Baranek et al. (1997) explored the relationship between tactile hypersensitivity and stereotypes and found that children with ASD and tactile sensitivity were more likely to exhibit visual stereotypes, behavioral rigidities, and repetitive vocalizations.

Tactile Defensiveness and Discrimination Test-Revised

Renee Watling

Division of Occupational Therapy, Department of Rehabilitation Medicine, University of Washington, Seattle, WA, USA

Synonyms

[TDDT-R](#)

Description

This tool is not currently available commercially. According to the published literature, the Tactile Defensiveness and Discrimination Test-Revised (TDDT-R) is comprised of multiple subtests with two of these measuring responses to light touch stimuli. These subtests involve applying light touch to various points on the

examinee's skin via a finger puppet/cotton swab or small stickers. The examinee is observed for behavioral reactions such as withdrawal from the stimulus, scratching or rubbing the skin, or negative facial grimaces. Intensity of responses is coded on a four-point scale with higher scores indicating more symptoms. Test items are administered with vision allowed for training purposes then with vision occluded for measurement of response. Other subtests measure orienting/habituation, tactile discrimination, and sensory seeking behaviors during play-based tasks (e.g., finding hidden objects and exploration of textures such as sand, lotion, etc.).

Scores can be calculated for accuracy of discrimination and for level of tactile defensiveness, under internally and externally controlled conditions. The manual is available from the author; no norms are currently published.

Historical Background

The Tactile Defensiveness and Discrimination Test-Revised (TDDT-R; Baranek 2010; Baranek and Berkson 1994) is a 15-min behavioral observation assessment of tactile processing (hyperresponsiveness and tactile discrimination) for children with autism and other developmental disabilities ages 2 through 14 years. This performance-based measure involves presentation of play-based tactile tasks and observing and coding responses.

Psychometric Data

This tool has been validated in several studies with children with autism, fragile X syndrome, and other developmental disabilities ages 2 through 14 years (Baranek and Berkson 1994; Baranek et al. 2002; Boyd et al. 2010; Watson et al. 2011). Inter-rater reliability has been documented as >90%.

Clinical Uses

This tool is not currently commercially available, so it is unlikely that it will be encountered in clinical practice. However, it continues to be used in research and may be encountered in the literature.

Definition

Our awareness of surrounding environments is perceived, keeping temporal continuity, which is important for constructing a robust representation of the environment. Temporal limitations to sensory information processing inhibit extraordinary inflow of sensory inputs. For example, in tactile temporal order judgment, in which sensory inputs are successively provided, temporal resolution (as a discriminative limitation) is approximately 50 to 100 (Ide et al. 2019; Takahashi et al. 2013; Yamamoto and Kitazawa 2001). This suggests that we roughly summarize sensory inputs that are delivered within a certain temporal range, as the information of a single unit because of temporal resolution and cognitive processing capacity limitations.

Buhusi and Meck (2005) presented a neural timing process framework which was further sub-divided into three different stages. The millisecond timing stage represents the shortest time scale for neural processing, at ≤ 1 s, and served speech and motor control functions. The stages in interval timing and circadian timing were longer at over ≥ 1 s and ≥ 1 h, respectively, and active

during decision-making, conscious time estimation, and the sleep-wake cycle.

Numerous reports have suggested the presence of enhanced perceptual functions in individuals with autism spectrum disorder (ASD). These enhancements may manifest as elevated detection and discrimination performance (Dakin and Frith 2005). Such studies mostly concentrated on spatial sensory processing, for example, detecting and searching for target stimuli amidst distractive stimuli (Bertone et al. 2005). Fewer works have examined perceptual ability in the temporal domain. Herein we overview studies which examined temporal processing in the brain in experimental psychological and neuroscientific review fields. We then introduce our ongoing studies which are examining the perceptual/cognitive characteristics of internal timing in individuals with ASD and the contribution of extraordinary temporal resolution to symptomatic sensory hyperreactivity.

Historical Background

Although temporal processing has garnered little attention in the autism literature, there is reason to believe that some individuals with ASD exhibit outstanding timing abilities in their daily lives. Colman et al. (1976) found that children with ASD manifested frequent repetitive behaviors and decreased attention to their jobs when they were in the presence of fluorescent lighting that flickered at 60 times per second, rather than incandescent lighting. Their findings suggested that some individuals with ASD possessed an extremely high temporal resolution (i.e., over 60 Hz of visual temporal resolution), sufficient to perceive flickering. This frequency of light flickering would be challenging for neurotypical individuals to identify. Another example is that individuals with ASD frequently complain of tactile hyperreactivity or perceived discomfort in response to skin contact with certain fabric

textures or clothing tags (Dunn 2001). Scratching the skin on a finely textured surface produces high-frequency vibrotactile information. Consequently, complaints of uncomfortable sensations in response to clothing scratches originate from the high temporal resolution of these tactile sensory inputs.

Perceptual time duration is another dimension which reflects temporal limitations for sensory stimuli processing. Honma et al. (2019) studied the accuracy with which individuals with ASD could reproduce various temporal durations. Participants were instructed to wait for an arbitrary time duration (10 or 20 s) and respond by tapping a tablet when they felt the instructed duration had elapsed from stimulus onset. Their results showed less accuracy of reproduction in individuals with ASD than neurotypical controls in their responses to shorter (10 s) duration conditions. Considering that higher individual deviations of reproduction performance in individuals with ASD were demonstrated in the auditory modality (Martin et al. 2010), they might have difficulty precisely identifying the temporal duration of sensory stimuli on an interval timing scale (Buhusi and Meck 2005).

The neural bases of stimulus temporal processing have been broadly surveyed in terms of stimulus duration or estimation of elapsed time from stimulus onset. The basal ganglia and supplementary motor area (SMA) are likely involved in modality-independent temporal processing of sensory inputs. Based on our neuroanatomical knowledge of information processing through the thalamo-cortico-striatal loop, the basal ganglia are suspected to play an important role in timing processes (Buhusi and Meck 2005). This circuit includes the prefrontal cortex and the posterior parietal cortex. Activation of these areas during interval timing tasks has been confirmed by prior investigations. The neural circuit between the cortices and the basal ganglia might form an internal clock for temporal processing (striatal beat frequency model).

Animal pharmacological studies have demonstrated that administration of a dopaminergic agonist (e.g., methamphetamine) into the striatum reduces the estimated time. Conversely,

administration of an antagonist (e.g., haloperidol) prolonged the time. Taken together, these findings suggest that the dopaminergic system can modulate the speed of “internal clock” (Meck 1996). A recent mouse study revealed that activation of dopaminergic neurons in the substantia nigra pars compacta (SNc), a part of basal ganglia, induced a longer estimation of stimulus duration. In contrast, inhibition leads to a shorter estimation of stimulus duration (Soares et al. 2016). Dopaminergic signaling from the ventral tegmental area (VTA) to the frontal cortices may also modulate time perception (Kim and Narayanan 2018). While it is still unclear that somatosensory temporal information could also be processed in the overlapped circuit, neurotransmission might be critical for precise duration or time estimation. Abnormal functioning of the prefrontal cortex and basal ganglia has been frequently reported in individuals with ASD and may lead to aberrant stimulus temporal processing (Allman and Meck 2012).

Current Knowledge

Many studies that used psychophysical techniques examined temporal resolution by evaluating perceptual/cognitive limitations to temporal discrimination of a sensory stimulus when another stimulus is delivered within a short temporal interval. During the simultaneous judgment (SJ) task, participants answer whether or not double stimuli, successively delivered with different short temporal time intervals, are perceived as synchronous or asynchronous inputs. During the temporal order judgment (TOJ) task, respondents judge the order of stimuli delivered during the SJ task. Tactile temporal resolution of normal participants was reported to be about 30–60 ms in response to SJ task of vibrotactile stimuli (Hirsh and Sherrick 1961; Miyazaki et al. 2016) and 60–80 ms in response to the TOJ task (Ide et al. 2019; Takahashi et al. 2013; Yamamoto and Kitazawa 2001). These data imply that different neural circuitry stages might link different tasks since few differences in tactile temporal resolution were reported relative to task features

(i.e., SJ or TOJ). A study that used the SJ task reported that visual temporal resolution was higher in individuals with ASD compared with neurotypical individuals (Falter et al. 2011). That is, individuals with ASD could finely discriminate double visual stimuli presented with short temporal lags. Another TOJ study showed that individuals with ASD manifested lower temporal resolution of vibrotactile stimuli than neurotypical participants; however, individuals with ASD exhibited higher temporal resolution when the stimuli were synchronously delivered with conditioning background stimuli (Tommerdahl et al. 2008).

One study demonstrated the neural correlates of neurotypical individuals during tactile SJ and TOJ using functional magnetic resonance imaging (MRI) (Miyazaki et al. 2016). The SMA and the basal ganglia showed heightened BOLD signals (as a proxy of neural response) during each task in comparison to the resting state. During between-task comparisons, greater activations of the bilateral insula cortices were shown during SJ rather than during TOJ tasks. Conversely, the bilateral dorsal premotor, the left ventral premotor cortices, the superior/inferior parietal lobule, and the thalamus exhibited greater activation during the TOJ task than during the SJ task. These brain regions may also be involved as TOJ neural circuits and during lateralization to the left hemisphere (Takahashi et al. 2013). Moreover, an essential role of neural activation in the parietal-occipital sulcus involving precuneus for proper task performance of TOJ has been shown (Takahashi and Kitazawa 2017).

Neural activation of the basal ganglia-cortices network may be important for tactile temporal resolution tasks as demonstrated in rodents (Kim and Narayanan 2018; Soares et al. 2016). Dopamine projections from the VTA to the cortex may modulate the frequency of cortical oscillations (Meck et al. 2013). Thus, the frequency of cortical oscillation depends on the dynamics of synaptic neurotransmitter and may in turn predict temporal performance. Assuming that a phasic neural oscillation reflects the perceptual processing cycle, stimulus temporal resolution is

likely to be modulated by the perceptual cycle. According to this Temporal Framing Theory (see a review in Baumgarten et al. 2015), if two stimuli were presented during one cycle of a neural oscillation, the stimuli would more likely be perceived as a single stimulus. On the other hand, if the stimuli were presented across two cycles, they would more likely be perceived as two separate stimulations. In line with this theory, faster parieto-occipital alpha-band oscillation predicted more accurate discrimination performance of two successive flashes (Samaha and Postle 2015).

Similarly, the phase of an alpha- or low beta- (8–20 Hz) oscillation in the primary somatosensory cortex predicted discrimination accuracy of electrical pulse stimulations (Baumgarten et al. 2015). A study of tactile TOJ using magnetoencephalography (MEG) demonstrated that the phase of alpha-band oscillation is crucial for proper order judgment (Takahashi and Kitazawa 2017). One recent study which examined the effect of transcranial alternating current stimulation (tACS) for tactile TOJ reported that a 10 Hz electrical stimulation of the bilateral posterior parietal cortices improved temporal resolution (Otsuru et al. 2019).

In line with these reported neural substrates of temporal resolution, Ide et al. (2019) demonstrated that diversity of tactile temporal resolution in individuals with ASD was associated with sensory hyperresponsivity, a diagnostic characteristic of ASD. In that study, participants performed a tactile TOJ task using vibrotactile stimuli. While the tactile temporal resolution of individuals with ASD did not differ from that of neurotypical controls, there was a significant positive correlation between temporal resolution and sensory hyperresponsivity severity assessed using the *Adolescent/Adult Sensory Profile* (AASP) (Brown et al. 2001). Individuals with ASD with higher temporal resolution during the tactile TOJ task tended to report more frequent pathognomonic experiences of sensory hyperresponsivity during their daily lives. In our unpublished study, we analyzed the neural correlates of an individual with ASD who showed extremely heightened tactile temporal resolution

and severe sensory hyperresponsivity. The patient's tactile temporal resolution was almost ten times greater than the controls'. As demonstrated by fMRI during a tactile TOJ task, the patient showed greater BOLD responses in the left superior frontal gyrus, the ventral premotor cortex, and the superior temporal gyrus than the control participants. Consistent with previous TOJ literature, greater activations were found in left hemisphere regions (Miyazaki et al. 2016; Takahashi et al. 2013). A group analysis that pooled all the participants showed that the percentage of correct responses positively correlated left superior frontal gyrus activation and negatively correlated with activation in the right inferior frontal gyrus. We speculated that increased and decreased neural activities in different parts of the frontal area regulated sensory input temporal resolution.

Future Directions

In addition to some studies that addressed characteristics of temporal processing in individuals with ASD, our research suggested individual differences in processing. We also found that excessively high temporal resolution engages diagnostic aspects of sensory hyperresponsivity. The findings may seem to counter previous reports that demonstrated lower accuracy of time reproduction of sensory stimuli, as discussed above (Honma et al. 2019; Martin et al. 2010). For the three stages of timing processes proposed by Buhusi and Meck (2005), the processing of ≤ 1 ms was assumed to be separate from processing of ≥ 1 ms. Studies that reported high temporal resolution in individuals with ASD, including our study, examined ≤ 1 ms millisecond timing processes using psychophysical tasks, such as SJ and TOJ. Such tasks reflect low-level sensory processing (Falter et al. 2011; Ide et al. 2019; Tommerdahl et al. 2008). In contrast, the studies that reported lower performance used second timing processes that were ≥ 1 ms (i.e., interval timing and circadian timing) during reproduction and discrimination tasks (Honma et al. 2019; Martin et al. 2010). These differences

of processing stage in terms of time perception might produce the apparently contradictory temporal resolution findings in individuals with ASD.

Alteration of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter, is likely the underlying basis of the considerably high temporal resolution of sensory inputs in individuals with ASD and may result in sensory hyperresponsivity (Cellot and Cherubini 2014). Reduced concentration of GABA or density of GABAergic receptors has been observed in broad brain areas of individuals with ASD. These findings suggest an imbalance between neural circuitry excitation and inhibition (E/I) (Cellot and Cherubini 2014). Development of proton magnetic resonance spectroscopy (^1H -MRS) has allowed researchers to perform in vivo measurement of brain metabolites. One study found that neurotypical individuals with higher frequency discrimination performance for vibrotactile stimuli showed lower GABA concentrations in the sensorimotor cortex (Puts et al. 2011). Future studies should examine GABA concentrations in the brains of individuals with ASD and determine if these concentrations are associated with temporal resolution task performance, which relates with sensory hyperresponsivity.

As mentioned above, individuals with ASD occasionally complain about the flickering of fluorescent lights and tickling sensations caused by touching of certain textures to their skin (Colman et al. 1976; Dunn 2001). These atypical perceptual/cognitive experiences may be related to the temporal resolution of sensory inputs. Individuals with ASD frequently report that their sensory hypersensitivity is affected by other psychological conditions, including high stress, anxiety, and so on. Thus, relationships with autonomic nervous system functions are suggested. Since researchers' interests is centered on the contributions of those psychological states to sensory hypersensitivity, revealing the effects of such states on psychophysiological task performance, including temporal resolution, should assist us in developing more effective clinical interventions.

Tardive Dyskinesia

Christoph U. Correll
Psychiatry Research, The Zucker Hillside
Hospital, Glen Oaks, NY, USA

Synonyms

[Antipsychotic-induced dyskinesia](#); [Chronic dyskinesia](#); [Irreversible dyskinesia](#); [Late-onset dyskinesia](#); [Neuroleptic-induced dyskinesia](#)

Definition

Tardive dyskinesia (TD) is a chronic extrapyramidal adverse effect, consisting of abnormal,

involuntary movements of the tongue, lips, face, trunk, and/or extremities. TD can either occur spontaneously or as an adverse effect during antidopaminergic therapy, particularly long-term antipsychotic treatment, but also after exposure to antidopaminergic medications inhibiting gastric motility (e.g., metoclopramide). The annualized TD risk in adults is approximately 5% with first-generation antipsychotics and $\leq 1\%$ with second-generation antipsychotics (Correll et al. 2004; Correll and Schenk 2008). In children and adolescents, mostly treated with low-dose risperidone, the annualized TD risk was 0.4% (Correll and Kane 2007). The exact pathophysiology of TD is still unknown. Increased TD risk is associated with older age, female sex, White ethnicity, history of acute extrapyramidal side effects, higher daily and cumulative antidopaminergic medication dose, and with first-generation versus second-generation antipsychotics (Margolese et al. 2005a). Patients with central nervous damage and those with preexisting motor abnormalities, such as are not uncommon in patients with autism spectrum disorders, may also be at greater risk for TD (Campbell et al. 1997; Connor et al. 2001; Masi et al. 2003). Measurement of TD severity and determination of TD caseness can be achieved with the Abnormal Involuntary Movement Scale (AIMS) (Guy 1976) or the dyskinesia subscale of the Extrapyramidal Side Effect Scale (ESRS) (Chouinard et al. 1980). The classic definition of TD according to the Schooler-Kane criteria consists of either a rating of mild (Schooler and Kane 1982) in at least two body regions or a rating of at least moderate (Chouinard et al. 1980) in at least one body area. In youth and adults, antidopaminergic treatment of at least 3 months is currently required to diagnose treatment emergent TD, while in the elderly the minimum treatment duration was set as 1 month. However, there is no known biological minimum or required duration of antidopaminergic exposure after which TD can emerge. Nevertheless, TD needs to be differentiated from withdrawal dyskinesia that follows during or closely after antipsychotic discontinuation (or switch), and that can last for several months. In youth, TD may be more reversible than in adults and, especially,

the elderly when discontinuing the offending dopamine blocking medication (Correll and Kane 2007). Except for discontinuing all antipsychotic agents or a switch from an antipsychotic to clozapine, no other treatment strategy has been found to be consistently efficacious for the treatment of TD (Margolese et al. 2005b). Sometimes, antipsychotic dose increase can mask abnormal involuntary movements.

Target Behavior

Stephanie Bendiske

The Center For Children With Special Needs,
Glastonbury, CT, USA

Synonyms

Challenging behavior; Skill; Unit of response

Definition

Target behavior is the behavior identified to be changed, the prescribed behavior. This behavior can be defined either by function or by topography. A functionally defined target behavior identifies a response by its effect on the person or the environment. For example, pica is defined by placing inedible items in the mouth and consuming them. In contrast, topographically based definitions identify a response by its form. Function-based definitions are preferable and should be used wherever possible because they lead to more accurate and reliable measurement systems and because they capture the response class more accurately.

Definitions

After it has been determined that a child qualifies for special education services, an Individualized Educational Program (IEP) is developed by the school with input from parents. The IEP is a written legal document that includes goals, the method for obtaining these goals, and a measurement plan. The term “social” is individually defined depending on the particular IEP goal of the child. For example, for some children appropriately taking turns during a simple activity is a social goal. For others, engaging in appropriate reciprocal verbal conversation is a social goal. Inclusive settings are community environments that have a natural proportion of children with autism spectrum disorder (ASD) or other disability and typically developing peers. In these settings, peers can be used as appropriate role models as well as providing support, participation, and assistance during goal implementation. Paraprofessionals are one-on-one assistants that generally do not hold an advanced higher education degree and are hired to assist and monitor students in the implementation of IEP goals. Paraprofessionals are supervised by individuals with advanced degrees, such as teachers in the school setting. Peer mediation refers to strategies in which peers

are recruited to assist with the implementation of target goals. Priming is a procedure wherein children are exposed to a concept or activity before it is presented in real time. The use of priming has resulted in improved learning and lower levels of disruptive behavior in academic and social settings. Pivotal Response Treatment (PRT) is an intervention package consisting of specific motivational components (e.g., choice, natural rewards, task variation, and rewarding attempts) that have been shown to improve responsiveness, learning, and decrease challenging behaviors when incorporated into the intervention. Ritualistic and repetitive behaviors (RRBs), sometimes referred to in the literature and in clinical practice as stereotypic behaviors or self-stimulatory behaviors, are idiosyncratic repetitive actions that may interfere with learning and socialization. Self-management is a procedure wherein children are taught to discriminate, evaluate, and then monitor their own behaviors. Self-management can be programmed to occur in natural environments, thereby reducing the need for constant vigilance by an adult or treatment provider.

Historical Background

By definition, all children with ASD have difficulty with social communication skills (American Psychiatric Association 2013), and thus, developing interventions for improving this area has been a major goal of treatment programs. Historically, children with ASD were excluded from the educational system because of the lack of effective interventions to improve social communication and other areas (cf. Koegel and Koegel 2019). However, in the 1960s, interventions documenting that these children could learn began emerging in the scientific literature.

During the mid-1970s, laws were passed requiring children with ASD to be included in school settings. Over time, it became evident that interventions for developing social behaviors would be of major importance, and the large number of typically developing peers might make the school setting an ideal place for social interactions. Although social goals were considered to be a

critical area, interventions remained a difficult and relatively undeveloped area in individualized educational programs (IEPs) for children with ASD. Impairments in social communication can lead to academic underachievement, a decrease or complete lack of employment later in life, and fewer opportunities to participate in leisure activities (Holwerda et al. 2012), among other challenges. Thus, the importance of targeting social goals is critical. Despite the fact that many children with ASD report a desire to have friendships (Bauminger and Kasari 2000), they often spend unstructured play periods alone and/or engaging in RRBs rather than socializing in school and other settings where peers are available. Another challenge is that while explicit individualized teaching of social skills is critical for these children (White et al. 2007), often the least trained individuals (e.g., paraprofessionals) are the only staff available to deliver social interventions during unstructured periods. In addition to the need for social intervention during the school year, a related concern expressed by parents and teachers is continuity of treatment and the lack of school services during summer months (Brookman et al. 2003). While many schools offer extended school year programs, these often are short term and do not include typically developing peers, that may be helpful for assisting with the social intervention and who serve as important role models.

Underlying Theory, Goals, and Objectives

The underlying goals and objectives of this research are based on the theory that ASD is largely a performance or motivational deficit rather than an ability deficit (Koegel and Egel 1979; Koegel and Koegel 2019). The theory suggests that children with ASD may acquire socialization skills such as asking a question or initiating to peers; however, they may not perform these skills due to a severe lack of motivation. We have discussed this as the child exhibiting learned helplessness (Koegel and Egel 1979; Koegel and Koegel 2019). Based on a theory of learned helplessness, we hypothesized that the children might actually be capable of performing certain

behaviors, but just do not perform them due to a severe motivational deficit and related difficulty in associating reinforcers with their behavior. We also hypothesized that if an empirically based intervention could be developed to motivate children with ASD to engage in social interactions, there would be rapid and widespread improvement in their behaviors rather than needing to teach the children to exhibit the behaviors one at a time over a long time period. Further, implementing such an intervention using empirically validated motivational procedures should improve socialization with widespread generalization (Koegel and Koegel 2019). Of specific relevance to this chapter is the hypothesis that if such motivational interventions could be implemented so as to target IEP goals throughout the day in summer camp, achievement of the IEP goals would be rapidly acquired, putting the children ahead of schedule. Finally, it has been hypothesized that as a result of massed practice in a setting such as a summer camp where interventions with motivational components could be implemented across settings and peers, generalization and maintenance of social skills would occur.

Treatment Participants

Individualized treatment packages for socialization, described herein, have been empirically shown to be effective with a wide range of children diagnosed with ASD (Koegel et al. 2019). The interventions have been individualized and therefore can be used with a wide age range of children enrolled in summer camps, including elementary school aged children through adolescence. Further, since target goals are individualized, the procedures can be used with a variety of ability levels ranging from minimally verbal children, whose goals may be focused on areas such as turn taking, to highly verbal children with ASD whose goals focus on verbal social communication. While the research on targeting IEP goals in summer camps has focused on children diagnosed with ASD who demonstrate social communication difficulties with peers, we speculate that the

procedures would also be effective with any child having difficulties socializing with peers.

Treatment Procedures

Interventions for difficulties in social communication frequently have been based upon a model of learned helplessness, where children are taught to attempt to make communicative responses, and then reinforced for making those attempts, even if the initial attempts are not entirely accurate. Reinforcing the children's attempts to socially communicate, rather than insisting on their performance of completely correct communicative responses, has resulted in the elimination of learned helplessness and in rapid and large increases in the children's social communication (cf. Koegel and Koegel 2012, 2019). While there is not one standardized model of teaching social skills, it is common for professionals to use motivational procedures and antecedent interventions. Social interventions can be adult-directed (e.g., "show me how you share the candy with your friends"), peer-directed (e.g., using a peer to prompt for turn taking), or child-directed (e.g., setting up an activity around the child's interests to capture motivation for initiations to peers).

Mechanism of Intervention. Related to the mechanism of intervention, by targeting goals in an inclusive camp setting, the children with ASD have extensive opportunities to be exposed to typically developing peer models who can also serve as intervention mediators. It is also noteworthy that paraprofessionals spend a large amount of their time in such inclusive settings and have the potential to be major treatment delivery agents if they were properly trained. Therefore, an additional goal of this research has been to assess whether paraprofessionals can effectively implement the interventions.

In the Koegel et al. (2019) study, participants attended a summer camp for 2 weeks. Intervention consisted of PRT and Positive Behavioral Intervention and Support (PBIS) strategies, which were individualized for each child and their specific social goal. The strategies were designed to eliminate learned helplessness and increase motivation

for social communication. The procedures included reinforcing attempts, using natural reinforcers, following the children's lead in order to identify motivational stimuli, priming, peer-mediated intervention, and self-management. Many of the activities organized by the camp (e.g., ropes, archery, and gymnastics) were new to the participants. Therefore, priming (Koegel and Koegel 2006; Koegel et al. 2003) was a method used to expose the children with ASD to activities before they encountered the activity with their peers in the summer camp. Specifically, the participants were provided with instructions and prompts to follow the rules of the activities (e.g., prompting the child to stand in line with friends and wait for their turn) to anticipate what was expected (e.g., when it's your turn you will get a safety harness and then you can climb up as high as you can).

In order to further promote participation in camp activities, typically developing peers selected based on their requests to assist the child with ASD were recruited to engage with the child with ASD. Paraprofessionals prompted the peers to initiate, take turns, participate in social conversations, and engage in social interactions with the participants based on each child's individualized goals. For example, when engaging in turn-taking, all of the campers were prompted to wait for their turns and to assist the child with ASD if necessary. Self-management, wherein the participants were taught to discriminate and record their occurrences or absence of targeted social behaviors (Koegel and Koegel 2006) was used during everyday activities with peers to increase targets such as social conversation.

We also anticipated that teaching the IEP social goals in an inclusive setting would be highly effective. Inclusive settings have been shown to be a beneficial setting to target social skills for individuals with ASD because willing peers can easily be recruited to model appropriate behavior and assist with intervention (Koegel and Koegel 2019; Rogers 2000; Watkins et al. 2014). Furthermore, peer-mediated interventions targeting social skills are more likely to generalize and maintain overtime when implemented in inclusive settings (Chamberlain et al. 2006; Watkins et al. 2014).

Efficacy Information

There has been a large amount of empirical research in the general area of social communication for children with ASD demonstrating gains if social areas are targeted (Koegel and Koegel 2019). Previous research on PBIS has consistently demonstrated that it is effective in reducing challenging behaviors for children with ASD (Carr et al. 1999; Koegel et al. 1996; Neitzel 2010; Turnbull et al. 2002). Further, PBIS and PRT strategies have been effectively implemented in summer camp settings by trained and supervised paraprofessionals to increase social skills and to reduce disruptive behaviors (Brookman et al. 2003). However, the feasibility of providing continuity with school interventions, by targeting IEP social goals for children with ASD during the summer has not been empirically addressed until recently (Koegel et al. 2019). In this current research on PRT, Koegel et al. (2019) collected data during behavioral observations for successive 10-min intervals during baseline, intervention, and follow-up. Each child showed gains and met their year-long IEP goals during the two-week intensive summer camp, only after the paraprofessionals providing the PRT motivational interventions reached fidelity of implementation. Specifically, whereas all children showed low levels to no social engagement during baseline probes, results demonstrated that following a 2-week summer camp program, with consistent targeted intervention using PRT, all participants made social improvements, reaching their year-long IEP goals within the 2 weeks, and that maintained at follow-up in natural nontreatment environments.

Outcome Measurement

There are various tools used to measure socialization outcomes. The most common method is collecting behavioral observation data on specific behaviors such as rate of initiations, percentage of engagement, level of enthusiasm, or frequency of turn taking. In the empirical research cited above, each participant received intervention during the

summer camp that was chosen from the child's IEP. Target outcomes included social engagement, appropriate eye contact during conversation, turn taking, and providing appropriate details when retelling a recent experience. Behavioral observations during 10-min representative probes were coded for each of the target behaviors. For example, within the probes, engagement was scored as appropriate if the participant engaged in the activity with peers and followed the rules of the game during successive 30s intervals. At the end of each session, the total number of intervals scored as appropriate was divided by the total number of appropriate and inappropriate intervals and multiplied by 100 to yield a percentage of appropriate engagement per session. By collecting frequent data on observable and measurable social behaviors in natural settings with peers, progress made on socialization goals can be evaluated.

Qualifications of Treatment Providers

Professionals who develop and supervise social skills interventions should have a background in the basic principles of applied behavior analysis, functions of behavior, and PBIS, as well as certification for meeting fidelity of implementation in PRT. The providers can include a variety of different people who are certified as proficient in PRT, including special education teachers, psychologists, BCBA providers, speech and language pathologists, and paraprofessionals. In the Koegel et al. (2019) study, one-on-one paraprofessionals supported the children with ASD throughout their camp day. The paraprofessionals were undergraduate students majoring in psychology who had taken an introductory undergraduate course in ASD. Graduate students with at least 4 years of experience working with children with PRT supervised the undergraduate students through in-vivo feedback for about 1 h per day. The graduate students were supervised by university faculty. While most adults, including parents with a relevant background in PRT, and students can deliver social skills interventions, it is important that a highly experienced professional is available to supervise, monitor progress, and provide feedback.

Summary

The results of the above empirical research suggest that inclusive summer camps may be ideal settings for targeting IEP socialization goals, even for just a few weeks, for children with ASD. One-on-one paraprofessionals can be taught to implement goals with fidelity of implementation; however, some background (i.e., coursework), on-site supervision, and ongoing training may be helpful. Overall, the research is optimistic that the important area of socialization may be improved during a short term and intensive intervention implemented by supervised paraprofessionals in a community summer camp setting with typical typically developing peers.

Task Analysis

Cathy Pratt¹ and Lisa Steward²

¹Indiana Resource Center for Autism, Indiana University, Bloomington, IN, USA

²Indiana Behavior Analysis Academy, Kokomo, IN, USA

A task analysis is used to break complex tasks into a sequence of smaller steps or actions. For some

individuals on the autism spectrum, even simple tasks can present complex challenges. Having an understanding of all the steps involved in a particular task can assist in identifying any steps that may need extra instruction and will help teach the task in a logical progression. A task analysis is developed using one of the three methods. First, competent individuals who have demonstrated expertise can be observed and steps documented. A second method is to consult experts in performing the required task. And finally, those who are teaching the skill can perform the task themselves and document steps.

As task analyses are developed, it is important to remember the skill level of the person, the age, communication and processing abilities, and prior experiences in performing the task. For those on the autism spectrum, also remember their tendency toward literal interpretation of language. For example, students who have been told to put the peanut butter on the bread when making a peanut butter and jelly sandwich have literally just placed the entire jar on the bread. Below are two examples of task analyses.

Putting a Coat On

1. Pick up the coat by the collar (the inside of the coat should be facing you)
2. Place your right arm in the right sleeve hole
3. Move your arm through until you can see your hand at the other end
4. Now reach behind with your left hand
5. Locate the left sleeve hole
6. Put your arm in the left sleeve hole
7. Move your arm through until you see your hand at the other end
8. Adjust the coat so it is ready to zip

Washing Hands

1. Turn on right faucet
2. Turn on left faucet
3. Place hands under water
4. Dispense soap
5. Rub palms to count of 5
6. Rub back of left hand to count of 5
7. Rub back of right hand to count of 5
8. Turn off water
9. Take paper towel

10. Dry hands to count of 5
11. Throw paper towel away

Skills taught using a task analysis (TA) include daily living skills, such as brushing teeth, bathing, making a meal, and performing a variety of household chores. Task analysis is also useful in desensitization programs such as tolerating haircuts, having teeth cleaned, and tolerating buzzers or loud environments.

Again, the number of steps involved and the wording used will differ depending on the individual. Determining the steps to a TA as well as the starting point for an individual often requires collecting baseline data, and/or examining the individual's ability to complete any or all of the required steps. Once implementation begins, the TA may need to be revised to address any additional needs. It is important that all steps are operationally defined.

Once a task analysis is developed, chaining procedures are used to teach the task. Forward chaining involves teaching the sequence beginning with the first step. Typically, the learner does not move onto the second step until the first step is mastered. In backward chaining, the sequence is taught beginning with the last step. And again, the previous step is not taught until the final step is learned. One final strategy is total task teaching. Using this strategy, the entire skill is taught and support is provided or accommodations made for steps that are problematic. Each of these strategies has benefits. In forward chaining, the individual learns the logical sequence of a task from beginning to end. In backward chaining, the individual immediately understands the benefit of performing the task. In total task training, the individual is able to learn the entire routine without interruptions. In addition, they are able to independently complete any steps that have been previously mastered.

Regardless of the strategy chosen, data has to be collected to document successful completion of the entire routine and progress on individual steps. How an individual progresses through the steps of the task analysis and what strategies are used have to be determined via data collection.

Definition

Treatment and Education of Autistic and Communication-related handicapped CHildren is an evidence-based service, training, and research program for individuals of all ages and skill levels with autism spectrum disorders. Established in the early 1970s by Eric Schopler and colleagues, the TEACCH program has worked with thousands of individuals with autism spectrum disorders and their families.

Description

The TEACCH Transition Assessment Profile (TTAP) by Gary Mesibov, John B. Thomas, S. Michael Chapman, and Eric Schopler (ProEd, Inc. 2007) is a revision of the *Adolescent and Adult Psychoeducational Profile (AAPEP)*. This test was developed for adolescents and adults with autism spectrum disorders, particularly those with transitional needs. The *TTAP* is structured to satisfy those provisions in the Individuals with Disabilities Education Act (IDEA) of 1997 that require adolescents to be evaluated and provided with a transition plan by age 14. In 2011, the *TTAP-CV: TEACCH Transition Assessment Profile, Second Edition – Computer Version* was published as a companion volume to the TTAP. This electronic version supports the development and documentation of goals for transition planning and career/job training with a detailed system of references and tools. These tools provide an opportunity for continuity in ongoing assessment throughout the adolescent and adult work history of an individual with ASD.

Educators, parents, counselors, and care providers can use this tool to assist individuals with autism spectrum disorders to prepare for independence in adult life (i.e., personal development, recreational living, adult integration into employment and residential arrangements, etc.). The *TTAP* will also help providers identify the individual’s principle transition goals, strengths, and weaknesses. Second, a “Cumulative Record of Skills” (CRS), along with several data collection forms, provides an efficient method of ongoing assessment in community-based instruction. The

TTAP can be used to facilitate educational and transitional planning. Emphasis is on evaluating multiple functional skill areas, including both concrete vocational skills and a variety of social, leisure, and conceptual skills that are crucial to effective vocational and residential training. The assessment instrument emphasizes:

1. Assessment for transition
2. Focus on the six major functional areas
3. Assessment and performance in different environmental contexts
4. A scoring system that assists goal development
5. Information on environmental accommodation
6. Identification of preferences for individuals with limited communication skills

Career planning is a lifelong process that requires repeated, ongoing assessment to adjust preferences and skills and to prioritize needs. The TEACCH Transition Assessment Profile creates a system that supports continuity of programming across the lifespan in defining and programming for positive adult outcomes.

The entire system of the TTAP allows users to record and update learner progress toward obtaining skills related to post-school outcomes.

The TTAP provides a way for users to generate reports about individual learners and to further identify necessary transition skills. The system lends itself to periodic review (e.g., the Individualized Education Program process).

Historical Background

In 1988, Gary Mesibov, Eric Schopler, Bruce Schaeffer, and Rhoda Landrus created *The Adolescent and Adult Psychoeducational Profile (AAPEP)*. This instrument was designed as a highly structured, skills-based instrument to evaluate current and potential skills in areas most important for successful independent functioning in the home and community. The instrument was intended to assist in diagnostic assessment as well as in defining objectives for instruction that would support independent community functioning.

As a result of nearly 20 years of supported employment services and adult residential

services provided by Division TEACCH, the instrument was redesigned to address the specific needs of individuals with autism spectrum disorders in transition services in public schools and in adult services, both residential and vocational. The skills-based instrument, the AAPEP, was redesigned to address a broader range of cognitive abilities. The “formal assessment” of the AAPEP was redesigned as an “initial assessment of transition needs,” as required by IDEA, the Individuals with Disabilities Education Act. Moreover, a significant expansion of the ongoing assessment process that is required by IDEA was added to assure that both school-based and adult service organizations had a means of documenting their programming and instruction.

The two instruments of the TTAP represent a means of direct experiential evaluation in adolescent and adult services. Inventory assessments, a primary form of adolescent and adult vocational assessments, are frequently ineffective in reliably measuring interests and employment potential for individuals with autism spectrum disorders.

Clinical Uses

The TEACCH Transition Assessment Profile provides both an initial assessment of transition needs and an ongoing documentation system that supports job development, job training, and supported employment service for individuals with autism spectrum disorders. The initial assessment of transition needs fulfills the requirement for such an assessment by age 16 for individuals requiring transition planning within the Individualized Education Program (IEP) process. It identifies potential educational objectives that can be reviewed by the IEP team. The ongoing assessment supports systematic instruction of specific objectives related to positive adult outcomes over the secondary school career of individuals with autism spectrum disorders. Moreover, the documentation system is easily transferred to adult service providers so that continuity of service provision can be addressed efficiently (Fig. 1).

overseen by professional consultants and should not be used without the guidance of a behavioral consultant or a speech-language pathologist.

Historical Background

The activities in *Teach Me Language* were reportedly developed over a number of years, following the authors' work on language difficulties for children with pervasive developmental disorders. No other historical information is available.

Rationale or Underlying Theory

Freeman and Dake (1997) suggest that there are no books that give hands-on, explicit instructions for working on the language needs specific to children with autism, Asperger's syndrome, and other related pervasive developmental disorders (PDDs). This was the impetus for their creation of a language manual that would provide exercises and drills to address those language weaknesses typically seen in children with PDDs. The manual capitalizes on the visual strengths reported for children with autism or autistic-like disorders as much of the material within the book uses visual scripts, word or phrase prompts, etc. (Freeman and Dake 1997).

Goals and Objectives

Teach Me Language focuses on six specific goals with chapters describing activities to address each of these goals. They are as follows:

- Improve social language: activities are designed to facilitate the child's ability to speak about a single topic as well as conversing with a peer.
- Increase comprehension and production of general information: activities are designed to support understanding of factual knowledge, an ability to compare and contrast concepts, defining vocabulary, and using true/false concepts based on general information the child learns.
- Improve use of grammar and syntax: activities are designed to facilitate understanding and use of the structure of language to create or assemble original sentences.

Teach Me Language

Danielle Geno Kent

The College of Arts and Sciences, The University of Vermont, Burlington, VT, USA

Definition

Teach Me Language (Freeman and Dake 1997) is a manualized approach to treatment designed to offer providers specific activities to support language understanding and use for children with autism spectrum disorders (ASDs). It is intended to be used as part of a therapy program already in progress that is

- Increase functional knowledge and written expression: activities are designed to improve recall and communication around personal, daily events.
- Increase language-based academic concepts: activities are designed to support comprehension of academic language, address math word problems, develop dictionary skills, and increase vocabulary related to money, time, calendar concepts, and numbers.

Treatment Participants

Teach Me Language was designed for the child who has already learned basic skills in lower-level language. Children who benefit most are visual learners, and those who can participate in table activities and are relatively compliant, and able to communicate in some way (Freeman and Dake 1997). Freeman and Dake (1997) suggest that the manual should be used as a supplemental support for in-place intervention. Children who are most likely to be responsive to the *Teach Me Language* activities would have a basic receptive and/or expressive vocabulary, i.e., knowing a few animals, basic shapes, and basic colors. They should also be familiar with the numbers 1–10 and recognize the alphabet.

Treatment Procedures

A written schedule is used during treatment to outline language therapy. The authors suggest that there is no developmental sequence to the activities provided; rather, the book is organized topically and should work in the context of the child's strengths and weaknesses. Each drill is introduced, and the child is prompted to give the correct answer. Prompts are faded over time so that the child completes most activities with few to no visual and/or verbal prompts (Freeman and Dake 1997).

Efficacy Information

The exercises in the manual were designed to be effective if the child understands that the therapist

is in charge and sets the agenda. *Teach Me Language* is designed to be used as part of an in-place therapy program. There is no specific research available addressing its efficacy although the principles guiding the activities are founded in behavioral research.

Outcome Measurement

Freeman and Dake (1997) suggest that once the child understands the concept emphasized during each exercise, the difficulty level of the exercise can be adjusted. If the child is struggling with a task after much repetition, then an easier drill is introduced. Children should demonstrate a level of mastery for each task as a sign of improvement.

Qualifications of Treatment Providers

The manual was designed to be used by parents, speech-language pathologists, and/or behavioral interventionists as part of an in progress treatment program where language difficulties are being addressed (Freeman and Dake 1997). The authors structured the book so that parents with minimal experiences could implement the language activities and drills without specialized training (Freeman and Dake 1997). However, the authors reinforce that although parents with minimal experiences could use the manual, they should do so only under the guidance of a behavioral consultant or a speech-language pathologist.

Teaching Abduction-Prevention Skills to Children with Autism

Metehan Kutlu¹ and Onur Kurt²

¹Department of Special Education, Hakkari University, Hakkari, Turkey

²Research Institute for Individuals with Disabilities, Anadolu University, Eskisehir, Turkey

Definition

Abduction is defined as “any unlawful movement or detention of a child, whether this is attempted or completed” (Collie and Greene 2016; Finkelhor et al. 2002). Children may be abducted by family members or strangers. Although most of the child abductions are committed by family members (Holcombe et al. 1995; Kurt and Kutlu 2019), child abduction by strangers can lead more serious results (e.g., sexual abuse, disappearance, death) in terms of child safety (Miltenberger 2008). A stranger is defined as “a person the victim has had no apparent previous contact or interaction with” (Collie and Greene 2016; Finkelhor et al. 2002).

Mostly child abductions are carried out by persuading the child or verbally enticing the child away from safety, without using physical force (Kurt and Kutlu 2019; Poche et al. 1981). Therefore, it is critical for children to learn how to protect themselves from abduction in order to prevent child abduction cases (Godish et al. 2017). The literature mentions several types of lures used by strangers to abduct children. Lure types are classified under four categories, including simple, authority, incentive (Poche et al. 1981), and assistance (Holcombe et al. 1995; Johnson et al. 2005). The simple lure involves

the request of anyone planning abduction from the child to come with him/her without any incentive or particular reason (e.g., “Will you come with me?”). The authority lure involves convincing the child using someone (e.g., parents, teacher) who has the authority over the child to come with him/her (e.g., “Your mom is looking for you, you must come with me now!”). The incentive lure involves giving something (e.g., surprise, gift, ice cream, candy) to the child if he/she accepts to come with the person planning the abduction (e.g., “I will give you candy if you come with me”). The assistance lure involves asking for the child’s help about something (e.g., “I lost my bunny, can you help me find it?”).

The abduction-prevention skill is defined as “learning what to do when a stranger tries to lure the child to go with him/her” (Tarbox et al. 2014). Acquisition of three behaviors by the child is aimed in teaching of abduction-prevention skills. These behaviors involve (a) clearly rejecting the lures of the stranger (e.g., reacting as “no or no way!”), (b) moving away from the stranger, and (c) telling/reporting about the situation to a family member or a trusted adult (Miltenberger 2008; Poche et al. 1981). Especially, “moving away from the stranger and reporting to a trusted adult” are the most critical components of these three target behaviors (Johnson et al. 2005). The child can avoid the dangerous situation to a great extent by moving away from the person planning to abduct him/her. The child reporting the abduction to a trusted adult can serve to bring the stranger who is planning to abduct him/her or has a tendency to do such an act under control (Miltenberger 2008).

Historical Background

Historically, specialists in the field of education stated that abduction-prevention skills are among the most critical skills due to their vital importance. The main purpose of the studies on abduction-prevention for nearly 50 years has been to protect children with or without developmental disability from physical, sexual, or emotional abuse.

The preliminary experimental research on teaching abduction-prevention skills was carried out during the 1980s. In the published articles, the skills of sexual abuse-prevention and abduction-prevention were focused on simultaneously (Miltenberger and Thiesse-Duffy 1988; Poche et al. 1981, 1988). The first experimental research focusing on protecting children from sexual abuse and abduction was published by Poche et al. in 1981 under the title of “Teaching Self-Protection to Young Children” in the *Journal of Applied Behavior Analysis*. In this study, a multicomponent training package based on a behavioral approach was used to teach normally developing children abduction-prevention skills. The training package included modeling, behavior rehearsal, and social reinforcement. It was observed that participants acquired avoiding strangers and generalized this behavior. However, maintenance data were collected from two of three participants, and only one participant exhibited the target behavior the criterion level in maintenance. The training package used in this research and similar training packages using more than one application together have been called as Behavioral Skills Training (BST) in later years and today (Miltenberger 2008). The specific interventions included in BST vary slightly, but generally role-play, rehearsal, and corrective feedback are involved in BST to teach abduction-prevention skills. In another study conducted in 1988, Poche et al. compared video modeling, video modeling with behavior rehearsal, a standard safety program, and no training in teaching children abduction-prevention skills. The video modeling with behavior rehearsal intervention in this research involved the components of video modeling, role-play, corrective feedback, and praise. In this research, although the best results were found in the video model plus rehearsal condition, some children in each condition accepted the proposal of the person planning the abduction. Therefore, it can be stated that none of the interventions were effective for all of the children. One of the remarkable aspects of this research was that the appearance of strangers in the video footage was presented to resemble those of adults who had previously been

convicted of child abduction and sexual abuse. In both studies, it was stated that children were vulnerable to lures of strangers and the need for educational programs was emphasized (Poche et al. 1981, 1988).

Studies by Poche et al. have been the basis for many other studies on the teaching of sexual abuse and abduction-prevention since the late 1980s (Bergstrom et al. 2014; Collins et al. 1992a; Gast et al. 1993; Gunby et al. 2010; Gunby and Rapp 2014; Haseltine and Miltenberger 1990; Holcombe et al. 1995; Miltenberger and Thiesse-Duffy 1988; Watson et al. 1992). Thus, these studies became a model for the teaching of abduction-prevention skills to individuals with normal development as well as individuals with developmental disabilities. In the 1980s and 1990s, BST was used in almost all of the studies on teaching abduction-prevention skills to individuals with normal development or developmental disabilities (Gast et al. 1993; Haseltine and Miltenberger 1990; Poche et al. 1981).

The first experimental studies on the teaching of abduction-prevention skills to persons with developmental disabilities were published in the 1990s (Collins et al. 1992a; Gast et al. 1993; Haseltine and Miltenberger 1990; Watson et al. 1992). To summarize the findings of these studies, it can be stated that BST was generally effective in teaching abduction-prevention skills to individuals with developmental disabilities, but in some studies, this finding could not be repeated consistently for all participants, and the participants of some studies had difficulty in maintaining their abduction-prevention skills and generalizing them to social environments (Collins et al. 1992a; Gast et al. 1993; Haseltine and Miltenberger 1990). In the 1990s, descriptive studies were conducted in addition to experimental research on teaching abduction-prevention skills to individuals with developmental disabilities. Descriptive studies showed that teachers and parents expressed that the skill of “resisting the lures of strangers” was a critical safety skill (Collins et al. 1991, 1992b). In 2000s, it was stated that learning abduction-prevention skills is vital for all children, but not enough attention was given to developing safety

skills training programs despite child abduction statistics (Johnson et al. 2005).

The first study aimed at teaching abduction-prevention skills for participants with autism was published in 2010 (Gunby et al. 2010). In this study and most of other experimental studies (Akmanoglu and Tekin-Iftar 2011; Bergstrom et al. 2014; Gunby and Rapp 2014; Gunby et al. 2010; Ledbetter-Cho et al. 2016), BST was used. To summarize the findings of these studies published since 2010, it can be stated that BST was effective in teaching abduction-prevention skills to children with ASD and that the participants of these surveys generally maintained target behaviors after the intervention ended and were able to generalize to conditions other than teaching conditions. In addition, there is no significant difference in the way BST is applied in the teaching of abduction-prevention skills to individuals with developmental disabilities, whether ASD or not, and normally developing individuals. BSTs, which consist of multi-component teaching packages used for teaching abduction-prevention skills to individuals with ASD, generally included applications such as instructions, modeling, rehearsal, and feedback (Bergstrom et al. 2014; Gunby et al. 2010; Ledbetter-Cho et al. 2016). However, in two studies published to date, video modeling (Godish et al. 2017) and social stories (Kurt and Kutlu 2019) were used instead of a multi-component teaching package. The findings of these two studies are similar to those of studies investigating the effectiveness of BST in teaching abduction-prevention skills to children with ASD. In other words, according to the findings of these two studies, video model teaching and social stories were also effective in teaching abduction-prevention skills to children with ASD.

As a result, the common element of published research on teaching abduction-prevention skill has been to teach children to recognize the lures of people who want to abduct them, to reject their offers, to move away from their environment, and to inform a trusted adult to control the situation. Teaching practices based on applied behavior analysis were mostly used in teaching these skills.

Current Knowledge

Millions of children disappear every year in the world ("International Centre for Missing and Exploited Children" 2019). According to a report published by the US National Crime Information Center (NCIC) in 2018, there were 424,066 entries for missing children in the United States. About 1% of these individuals had physical or intellectual disabilities. According to the same report, 4925 of these missing children may have been abducted ("Federal Bureau of Investigation" 2019).

The inability of children to protect themselves from abductors may facilitate their abduction. Unfortunately, children with disabilities are at a greater risk of being abducted compared with normally developing children (Godish et al. 2017). The difficulties or delays in communication skills and inabilities in attention, motor control, and cognitive skills that are experienced by children especially with ASD might increase the risk of getting harmed by their environment (Wiseman et al. 2017). Another risk factor is that almost 50% of children with ASD tend to elope from the safe area (Anderson et al. 2012). This situation increases the risk of harm and abduction of children with ASD. Moreover, children with ASD may not be able to distinguish strangers from acquaintances or may be prone to persuasion by strangers due to their inadequacy in social skills (Gunby et al. 2010). Recent studies have shown that children with ASD are more likely to believe and be abducted by lures offered by strangers (Akmanoglu and Tekin-Iftar 2011; Bergstrom et al. 2014; Godish et al. 2017; Gunby and Rapp 2014; Gunby et al. 2010; Kurt and Kutlu 2019; Ledbetter-Cho et al. 2016).

In the literature, the most commonly used method for teaching abduction-prevention skills to children with ASD is training packages, often called BST, where multiple applications are used together. Such a training package can be implemented as in the following example: Firstly, verbal instructions are given (briefly discuss/review the lures and safety response with participant); in other words, the practitioner

informs the participant about the behaviors to be exhibited (e.g., “If a stranger tries to get you to go with him/her, say ‘no,’ move away, and then tell your mom”). Secondly, the practitioner models the correct behavior (e.g., “Practitioner says “No” to abductor, moves away from him/her, and reports the situation to a trusted adult”). Thirdly, role-playing is carried out. In role-playing, the practitioner pretends to be an abductor with the child (“Let’s pretend we are at the supermarket and I’m a stranger”) (Bergstrom et al. 2014). Finally, praise (e.g., thank you for telling me) or corrective feedback is used depending on the child’s performance. Corrective feedback is used when the child does not exhibit the correct behavior at the criterion level (e.g., “You need to walk away from her”). BST training packages might also involve systematic clue and fading processes such as graduated guidance (Akmanoglu and Tekin-Iftar 2011) and constant time delay (Bergstrom et al. 2014). Another application that has been used so far in teaching abduction-prevention skills to children with ASD is video modeling. Video modeling was used alone in one study (Godish et al. 2017) and in combination with other practices within BST in some studies (Gunby et al. 2010; Gunby and Rapp 2014; Ledbetter-Cho et al. 2016) to teach abduction-prevention skills to children with ASD. In the studies using video modeling, video images of abduction-prevention skills exhibited by peer models were shown to children with ASD, and then the participant was given the opportunity to exhibit the same behavior. In a recent study on teaching abduction-prevention skills to children with ASD, social stories were also used (Kurt and Kutlu 2019). In this study, the lure types mentioned in the literature and the expected behaviors of the child with ASD were expressed in short sentences in the story, and these sentences were supported by photographs with peer models (Kurt and Kutlu 2019). An example sentence of a social story about target behavior can be written as follows: “When a person I don’t know wants me to go with him/her by saying that he/she will give me candy, I should go away by saying “no” to him and then tell my mom about it.”

Teaching Abduction-Prevention Skills to Children with Autism, Table 1 An example of scoring charts for teaching abduction prevention skills

Behavior	Score
Agreed to leave with the abductor	0
Did not agree to leave but failed to say “no”	1
Said “no” but did not leave or report the incident	2
Said “no” and left the area but did not report the incident	3
Said “no,” left the area, and immediately reported the incident	4

In published studies, scoring charts were generally used to evaluate the performance of children with ASD on abduction-prevention skills (Johnson et al. 2005). An example of such a chart is presented in Table 1 (Gunby and Rapp 2014).

The following recommendations may be taken into account in the organization of settings and planning of the teaching process for teaching abduction-prevention skills to children with ASD: Firstly, the types of lures (assistance, simple, incentive, authority) mentioned in the literature should be taken into consideration when evaluating the performance of children with ASD on abduction-prevention skills. Children with ASD may be overly sensitive to certain objects, foods, or activities (e.g., going to pizza, playing the piano). Various data collection methods (e.g., family interviews, observations) can identify objects, foods, or activities that children with ASD may be susceptible to. In this way, the performance of children with ASD in terms of incentive lure type can be determined better. Secondly, children with ASD may have difficulty in generalizing their newly learned skills to different settings and people (Dufour and Lanovaz 2017). Therefore, the implementation of efforts on teaching abduction-prevention skills to children with ASD in social settings may facilitate the generalization of these skills. Finally, children with ASD can often perceive visual stimuli more easily than auditory and social stimuli (Nikopoulos and Keenan 2006). Thus, visual aids can be utilized in the teaching programs related to abduction-prevention skills.

Future Directions

Despite its vitality, a limited number of studies have been conducted on teaching abduction-prevention skills to children with ASD. Therefore, the search for the development of more effective and efficient practices for teaching these vital skills to children with ASD should be continued. Future studies might aim at determining and using more efficient practices that can result in better learning. Better learning means that one particular teaching practice results in faster acquisition, higher generalization, and more comprehensive learning than the other (Tekin-Iftar and Kircaali-Iftar 2013; Wolery et al. 1991). In further research, studies can investigate which of the applications used in teaching abduction-prevention skills to individuals with ASD can be more effective and efficient.

Almost all of the published studies used BST, which was created by combining multiple applications, and children with ASD often learned socially valid and important target skills in these studies. Only two studies used social stories and video modeling instead of BST consisting of multicomponent training packages (Godish et al. 2017; Kurt and Kutlu 2019). However, the findings of these studies should be supported by other studies in order to generalize them. Although BST applications, which consist of multicomponent training packages, generally seem to be effective, studies comparing various teaching practices with each other can be planned in order to determine the teaching practices that can be used more effectively and efficiently in teaching abduction-prevention skills to children with ASD. Faster, less time, fewer teaching sessions, less error response rates, and less practitioner preparation have been used as productivity parameters in a large number of researches published so far (Tekin-Iftar and Kircaali-Iftar 2013; Wolery et al. 1991). Therefore, these efficiency parameters can also be used to determine which teaching practices are more efficient in teaching abduction-prevention skills. Moreover, although it has been determined by various studies to be effective, in some studies the BST packages required the use of intrusive adult prompts and more training time

and a higher level of expertise for practitioners (Mancil et al. 2009). Further studies may aim to determine the applications that can be used easily and effectively by nonspecialists (e.g., siblings, parents, caregiver) who are less intrusive to children with ASD.

To prevent the abduction of children with ASD by family members may be planned in future studies. In addition to strangers and family members, children can be abducted by people they know less (Finkelhor et al. 2002). Examples of slight acquaintances include the neighbors that the child never talked to before, house cleaner, a person that the child interacted online for less than a month, or a friend of a friend who once babysat for the victim. Therefore, it is important to conduct studies to protect children with ASD from strangers and family members as well as lures of slight acquaintances.

In studies focused on teaching abduction-prevention skills, children with ASD were taught to protect themselves from strangers who do not use physical force. However, children with ASD can also be abducted by force. Forced abduction can be carried out by strangers, family members, or slight acquaintances. New digital technology tools can be used to prevent situations where children with ASD can be abducted by force. For example, devices with GPS (Global Positioning System) (e.g., tablets, smartphones, smart watches) can show where children are when they are lost or kidnapped. In further research, the use of such technological tools to prevent the abduction of children with ASD can be studied. For example, children with ASD may be instructed to secretly activate the GPS use of smart watches during abduction. Another technology used in the teaching of children with ASD is virtual reality. Virtual reality can reduce the difficulties involved in providing the necessary environments and the sufficient number of people to play the role of strangers, when teaching abduction-prevention skills especially in social settings. Therefore, in further research, the use of virtual reality in teaching abduction-prevention skills can be studied. Moreover, the performance of children with ASD in real environments can be compared to that of virtual reality environments.

In the studies focusing on the teaching of abduction-prevention skills, practitioners have been professionals, and no study has been found in which parents or other family members participate in the teaching process. Participation of family members in the teaching process contributes to the maintenance and generalization of children's acquired skills at home and thus improves the quality of the process. Previous studies show that parents are able to teach many skills to their children, including self-help skills, communication skills, imitation skills, social skills, and joint attention skills (Besler and Kurt 2016). Therefore, family education studies aiming to teach abduction-prevention skills to children with ASD can be carried out, and studies on the effectiveness of teaching offered by family members can be performed.

In addition to children with ASD, parents may be affected by abduction and teaching sessions planned to teach abduction-prevention skills. In particular, children may feel more scared, cautious, or upset, as they are exposed to abduction trials in the experimental process of research (Godish et al. 2017). Therefore, it may be important to collect social validity data from both children with ASD and family members and to take into consideration the findings obtained from these studies in order to evaluate such effects (Callahan et al. 2017).

Teaching Interaction Procedure

Mitchell Taubman
Actum Clinical and Behavioral Services,
Calabasas, CA, USA

Definition

The teaching interaction procedure (TIP) is an applied behavior analysis (ABA)-oriented, systematic instructional procedure of the modeling, practice, and feedback sort. While it, at its core, does contain the basic elements (instruction, opportunity to perform the behavior, and feedback) of discrete trial teaching, the TIP contains additional components, is more complex, and is delivered in a more natural conversational and interactive manner. It has been utilized for nearly four decades with individuals with autism spectrum disorder (ASD) but has been empirically validated only in the last decade. It can be utilized to teach a variety of skills but is especially suited for instruction in the social area.

Historical Background

The TIP was developed in the early 1970s as part of the teaching family model for court-adjudicated

youth (Phillips 1968). It was based on the instructional style used by Lonnie and Elaine Phillips, who served as the original teaching parents in the first community-based ABA-oriented treatment program for delinquent youth, achievement place. Subsequent research showed it to be an effective technique for addressing the skill deficits of that population (e.g., Minkin et al. 1976).

In the late 1970s, it was brought by the author to the UCLA Young Autism Project and has been utilized in home, clinic, school, community, residential, and vocational settings to teach a variety of skills to children, adolescents, and adults on the autism spectrum in the years since.

Rationale or Underlying Theory

Years of field testing as well as a growing body of empirical support have shown that the TIP can be an effective means for developing competencies, in persons with ASD. The nature and components of the procedure allow for instruction in skills from the simple to the complex and sophisticated. Further, as it constitutes a naturalistic and dignifying teaching technique, it has been found to promote independent skill utilization, generalization, and consumer satisfaction.

Goals and Objectives

Often used in conjunction with motivational arrangements (e.g., token economies), the TIP is designed to help address skill deficits (e.g., social, play/leisure, communication, vocational, self-help) in the repertoires of individuals on the autism spectrum. It can also be effectively used to teach replacement and alternate skills to the behavioral excesses (e.g., noncompliance, poor frustration tolerance, negative attention seeking) common to ASD. The ultimate goal of the TIP is to produce meaningful skills, utilized independently in everyday, naturally occurring situations.

Treatment Participants

Because of the interactive and conversationally oriented nature of the TIP, it is typically used with those at the upper end of the autism spectrum. At least moderate communicative and social interaction skills are necessary for adequate participation in the TIP. Further, cognitive capacity of participants allowing for the understanding of such concepts as cause and effect and the relationship between role play practice and the ultimate utilization of skills are typically helpful. The procedure has often been used with young children but, because of its dignifying nature, is particularly fitting for adolescents and adults.

Treatment Procedures

The multistep TIP consists of the following components.

Label and Identification

The first step of the TIP is the labeling and identification of the target behavior or skill. Identification and labeling of a skill involve noting what is being taught and giving it a name. The purpose of this step is to make sure that the learner clearly understands what skill is being taught. Further, having a clear name for the skill can help when priming is used and makes for clear feedback. Several things characterize a good label. The label should be clear. It should capture the skill being taught and do so in as few words as possible. Also, it should consist of language that fits the age level and peer culture of the learner. When identifying the behavior, it is good practice to define what the behavior is and what it is not. Further, such identification should clearly indicate where and when the skill is relevant or an issue. Identification can relate the skill to the student's past history and personal experience. Past or present occurrences or issues in the child's life that point to the area of need can be included (e.g., "Remember when your classmate offered to give you help? Well, we want to work on what to do when that happens.").

Rationale

The second, and a unique component of the TIP, is the provision of a meaningful rationale. A rationale is not just a reason to engage in the behavior but rather naturally occurring, fundamental, and germane to the learner's purpose for engaging in the behavior. ABA often discusses the natural consequences of a behavior, such as when it is recommended that artificial reinforcers (e.g., tokens) be faded to natural, maintaining consequences. These natural consequences should form the substance of rationales. A good rationale includes naturalistic and realistic outcomes and meets the learner's personal needs and desires. This can be the first step in connecting the learner to the natural consequences that will eventually maintain the behavior. This connection will happen once the learner is good enough at the skill being taught to actually achieve those outcomes.

With rationales, learners are more likely to accept instruction. Further, they begin to recognize that they have influence over the outcomes they experience. Good rationales help the learner anticipate outcomes and develop a sense of cause and effect. With time and some teaching, some learners even begin to develop meaningful rationales themselves.

Description/Demonstration

The third component of the TIP is the description and demonstration of the skill being taught. Typically, given the complexity of skills often targeted, only part of a skill is taught in a single TIP session. It is very common that adjustments have to be made in the size or complexity of the segment, once the TIP begins.

The teacher should describe the segment being taught, including all necessary elements. This information might include what is being said and how it is being said – that is, facial expressions, voice tone, gaze, and body language. It may include overt actions, supportive elements (e.g., use of stress management tools such as taking deep breaths), and internal, cognitive pieces (e.g., self-talk or self-instructions). Descriptions should be detailed and

clear. They should also contain understandable, student-friendly language.

In the demonstration portion, the teacher models for the learner all of the components contained within the description. Modeling provides an exact demonstration of the behavior, or component, to be learned. Demonstrations are usually in vivo (happening live in front of the learner) but can be written, pictorial, or consist of video modeling.

Practice

The next step of the TIP is the practice or role play portion. It is critical to learning to make sure that the student has sufficient opportunity to practice the skill and that practice continues until the skill is mastered. What is practiced follows the description/demonstration. That is, attempts should be made to have the learner fully practice what has been modeled.

The student role plays the skill (or, more likely, the portion of the skill) being taught, with the teacher as partner, in a simulation. The teacher should design this step of the TIP in a way that will increase the chance that the student's practice will be successful. Therefore, the practice is most often initially removed from natural circumstances (hence it is role play) and setup in a way that will minimize the obstacles to successful performance. The teacher has control over the form and extent of the practice through setup and planning and by how he or she plays the other party in the role play. In this way, statements, styles, complexity, challenges, emotional content, and other factors can be adjusted either up or down. In time, effort is directed at working the fully learned skill into application in the natural environment.

Feedback

Without feedback, indicating what was correctly performed and what was less than adequate, practice may not result in progress. Without feedback, practice can be an exercise in repetition of mistakes and can result in frustration.

Feedback can be given throughout the TIP. Such feedback often focuses on the student's behavior and quality of their responses during the TIP. For example, this can include his or her cooperation, effort, calmness, participation, processing, persistence, patience, and attention.

The feedback step of the TIP, however, follows the practice. In it, the teacher provides specific feedback on the student's performance, both positive and corrective. The key is specificity: information on how the learner performed all (or as many as possible) of the components that were described and demonstrated should be provided. Positives should be sincere, accurate, and specific. Corrective feedback should be unambiguous, yet supportive and constructive.

Feedback may cycle back to the description/demonstration portion of the TIP as indicated. Opportunities for additional practice (with additional feedback) often follow. There may even be a return to the rationale, with reasons given for the correct performance and for the inclusion of the particular element being retaught. Typically, this would then be followed by additional modeling and practice as indicated.

Optional External Consequence

Often the feedback segment of the TIP is accompanied or followed by the giving of external reinforcement. Such reinforcement may take the form of tokens; direct reinforcement with items, activities, or opportunities; use of a contingency contract; or provision of other artificial motivators. It could involve reinforcement of correct performance of the skill being taught and/or appropriate learning behaviors as noted above.

The provision of external consequences may serve important motivational functions. While praise and positive feedback may have some value for the student with ASD, they may not be sufficient to motivate participation, performance, and skill acquisition. Without sufficient motivation, learning and application of new skills may not occur. Conversely, without skill instruction, all of the motivation in the world is not likely to result in changed performance. Systematic

instruction and consequences are two mutually facilitative and essential components of any ABA teaching procedure. Using external, meaningful consequences can help ensure that the student is motivated to learn and to eventually engage in the targeted skill in naturally occurring situations.

Given their potential benefits, external consequences can be a customary part of the TIP. The application of this component, like all good ABA, depends on the student, what has unfolded during the teaching, and flexible decision-making on the part of the teacher. In time, the goal is to fade the external consequences. This would occur when natural positive consequences (those outcomes introduced when rationales were provided) begin to control and support the utilization of the new skill.

A more extensive description of the TIP is provided in Taubman et al. (2011) and in Cihon et al. (2017).

Efficacy Information

Leaf et al. (2009) provided the first empirical evaluation of the TIP with individuals diagnosed with ASD. That study demonstrated that the TIP was effective for teaching all of its young participants targeted social skills; however, no generalization measures were collected, and maintenance measures were variable. In a follow-up study, Leaf et al. (2010) demonstrated the effectiveness of the TIP in teaching social skills within a group instructional format for individuals, ages ranging from 4 years old to 6 years old, diagnosed with ASD. Leaf et al. (2012) and Kassardjian et al. (2014) in studies comparing the relative effectiveness of the TIP to Social Stories™ both showed the TIP to be more effective and more facilitative of generalization when used to teach individuals with ASD social skills. Kassardjian et al. (2013) showed the successful generalization of social skills taught using the TIP to the natural environment with four individuals with ASD, ages ranging 4–13 years old. Ferguson et al. (2013) effectively used the TIP with video games to teach six children diagnosed with ASD, ages

7–11 years old, team sportsmanship skills and demonstrated generalization of skills taught. Peters et al. (2016) extended Leaf et al. (2010) by demonstrating the effectiveness of the TIP implemented in a group instructional format to improve social skills for four individuals, ages 8–10 years old, diagnosed with ASD. They also showed the maintenance over time of acquired skills and the social validity of the TIP. Ng et al. utilized a modified version of the TIP to effectively teach social skills to four children diagnosed with ASD and an intellectual disability. Finally, Green et al. (2019) illustrated the effective use of the TIP to train staff in the implementation of the TIP with children with ASD.

Outcome Measurement

Results of the use of the TIP can best be assessed through the use of observational measures. For such measurement, brief but clear definitions of appropriate or successful performance (again including all aspects) of the elements, segments, or components of the targeted skill should be created (often referred to as a task analysis). Measures typically involve the recording of the number of elements or segments of the targeted skill successfully learned or performed. A percentage reflecting the number of elements correctly performed divided by the total number of segments is then reported. While such measurement can certainly occur during contrived or training arrangements, it is suggested that ultimately, non-intrusive observation of independent skill performance should occur in natural everyday social situations. Only then can meaningful, true mastery, and actual, independent skill utilization be determined.

Qualifications of Treatment Providers

Those using the TIP should be well trained in the procedure. The training should include didactic instruction on the components of the TIP and their purposes as well as experiential training on its implementation. Training should not only

include application of the steps of the TIP but the manner in which they are delivered. Given the nature of the TIP and the capacity of those typically receiving the procedure, stylistic elements, flexibility in delivery, and concurrent rapport building are particularly important for instructional success. Accompanying training on the TIP with supportive background information on ABA and its basic principles and concepts can provide context and also be helpful.

skills considers the developmental and cognitive level of the child, and instruction can begin with very young children.

Historical Background

Childhood sexual abuse is a serious issue in the United States (USA). The latest figures estimate that approximately 57,964 children were confirmed victims of sexual abuse last year in the USA (US Department of Health and Human Services 2019). According to results from three administrations of the National Survey of Children’s Exposure to Violence, Finkelhor et al. (2014) reported an estimated prevalence of 27% for females and 5% for males, or approximately 1 in 4 girls and 1 in 20 boys. The results of CSA on youth are far reaching and can cause a multiplicity of emotional and behavioral problems into adulthood (Pérez-Fuentes et al. 2013). While all children are at risk of victimization, there are some characteristics that make certain children more vulnerable to sexual assault. One of those characteristics is the disability that children may experience, such as autism spectrum disorder (ASD). Certain social-emotional and communication challenges, when present in children with ASD, may be interpreted by sexual offenders as vulnerabilities that they can exploit (Edelson 2010). Research has confirmed that children with disabilities are 2–3 times more likely to be sexually abused (including raped) than children without disabilities (Brown-Lavoie et al. 2014; Sullivan and Knutson 2000). Mandell et al. (2005) found that 16.6% of caregivers reported their child with ASD had been sexually abused. Brown-Lavoie et al. (2014) reported that 78% of their respondents with ASD reported at least one instance of sexual victimization, compared to 47% of a comparison group. There appears to be certain characteristics that children with ASD possess that may make them more vulnerable to abuse including lack of communication, limited understanding of personal boundaries, and difficulty interpreting others’ intentions. Muccigrosso (1991) discusses other attributes of children with disabilities that may put them

Teaching Personal Safety

Maureen C. Kenny
Department of Counseling, Recreation and
School Psychology, Florida International
University, Miami, FL, USA

Definition

Teaching personal safety skills involves educating children about their private body parts, boundaries with others, personal privacy, and ability to say “no” to touches they do not want or are inappropriate. Conceptualized as part of childhood sexual abuse (CSA) prevention, educating youth about personal safety typically consists of teaching children knowledge and skills related to recognizing, responding to, and reporting potentially abusive situations (three R’s of prevention). Teaching personal safety

at increased risk including lack of knowledge of abuse, socialized to be over compliant, limited or no assertiveness/refusal skills and a potentially restricted range of socialization experiences. The later may lead them to accept professed affection/attention from people who may exploit them sexually.

In response to the growing body of knowledge regarding the scope and consequences of CSA, prevention programs were developed in the late 1970s and widely disseminated in the early to mid-1980s (Wurtele and Kenny 2010). The primary focus of CSA prevention efforts has been to educate children about how to protect themselves through group-based instruction on personal safety. These efforts have traditionally taken place in educational settings, as schools' primary function is to inform and educate (Wurtele and Kenny 2010). These school-based programs typically teach children safety rules, body ownership, private parts of the body, distinguishing types of touches and secrets, who to tell, and where to go for help. A systematic review by Walsh et al. (2015) found that these programs assisted children in learning behaviors that would help them avoid sexual abuse encounters, and that participants remembered what they learned up to 6 months after the program. In addition, participation did not increase fear or anxiety among participants, and those who participated were more likely to tell an adult about abuse compared to those who did not participate in a program. While these programs have existed for some time, there has been little focus on development of programs for children with disabilities, including those with ASD.

Current Knowledge

Prevention programs have historically not made accommodations or addressed children with disabilities, and limited research exists on CSA prevention programs with individuals with developmental disabilities (Lee and Tang 1998; Lumley et al. 1998). There have been a few studies, mostly conducted in the 1990s, using personal safety skills programs with children

with disabilities, but not specifically ASD (see Kim 2010), and only a small number of programs have received empirical support. There are even fewer programs that specifically target the parents of youth with ASD to assist with prevention education and little empirical evidence exists for these programs also. Given the lack of research with children with ASD and personal safety, a few personal safety programs for individuals with intellectual or other disabilities will be examined for potential generalization. It should be noted that in a review of programs that teach abuse protection skills to individuals with disabilities, only one utilized children while all other programs focused on adults (see Doughty and Kane 2010).

There are a few documented cases of teaching body safety skills to youth with disabilities and they have primarily utilized behavioral approaches. Lee and Tang (1998) used Behavioral Skills Training (BST; Wurtele 1986) with Chinese adolescents with mild mental deficits. BST has been empirically supported and is recognized by the California Evidence-Based Clearing House Practices as having promising research evidence as a primary prevention program for abuse. BST includes components such as instructions, modeling, rehearsal, praise, social reinforcement, shaping, and corrective feedback. The teens participated in two 45-min sessions where they practiced discriminating between appropriate and inappropriate touch requests and were taught four self-protection skills: verbal response (e.g., say "No!" in a loud voice), motoric responses (e.g., try to get away or remove yourself from the situation), tell some trusted persons (e.g., parents, teachers) about the incident, and report the person and situation concerning the sexual advance (Lee and Tang 1998). The teens evidenced increases in recognition of appropriate touch and did not over generalize appropriate touches to necessary medical or hygiene touches. They also demonstrated better understanding of sexual abuse issues (e.g., being boss of one's own body, knowing that adults' inappropriate touching of a child is never the fault of a child, touching an adult's private parts is wrong, touching own private parts is acceptable) and differentiating between

inappropriate and appropriate touch situations. Compared to a control group, they were also significantly more likely to verbally refuse inappropriate sexual advances, remove themselves from the abusive situations, tell a resource person about the inappropriate situations and relay what had happened to the resource person. Since some gains were not maintained at 2 months, the authors recommend booster sessions with an emphasis on the nonverbal refusal skill of physically removing oneself from the abusive situations. BST was also implemented with a young boy with ASD, and he made gains in knowledge of personal safety including appropriate touches (Kenny et al. 2013). His caretakers participated in a simultaneous program aimed at helping them create a safe environment for him and review the prevention concepts at home.

Moving beyond youth, Miltenberger et al. (1999) provided ten behavioral skills training sessions (1 h a week) followed by in situ training to five adult females with mild or moderate intellectual disabilities. Training involved presentation of information about sexual behavior and sexual abuse, learning to discriminate sexual abuse from harmless situations, instructions in the use of the sexual abuse prevention skills in response to a sexual solicitation from a staff person, rehearsal of the skills in role plays of a sexual solicitation, praise for correct performance and corrective feedback as needed, and the use of multiple exemplars of sexual solicitations in the role play. The sexual abuse prevention skills taught were not complying with the request, saying “no” (or its equivalent), leaving the area, and reporting the incident to an authority figure. Behavioral skills training resulted in abuse prevention skill acquisition and in situ training produced generalized responding during naturalistic assessments (Miltenberger et al. 1999).

Using a more cognitive, decision-making approach, Khemka and Hickson (2000) used video vignettes with adults with intellectual disabilities that showed potentially abusive situations (e.g., sexual, psychological, and physical). The vignettes were short video clips (<1 min) and included a visual scene overlaid with a verbal narrative. The scenes were problematic real-life

social interpersonal situations that required decision-making by the individual. All participants scored high in their ability to successfully recognize and define a situation involving abuse as a problem situation. However, rather than act independently, the individuals often wanted to seek help from an authority figure. While these are still prevention efforts, they are not as immediate as taking action themselves. These authors recommend that the focus of abuse prevention training should be on fostering independent, generalizable, self-regulatory skills, such as decision-making, assertiveness, and self-empowerment.

Teaching methods need to be adapted to the level of functioning of the target individuals. The concurrent deficits in communication, social skills, and behaviors – which accompany ASD – will have to be considered when creating personal safety training programs. Several materials and curricula exist that may be helpful in training but have not been empirically evaluated. Susan Ludwig’s book, *Sexuality: A Curriculum for Individuals Who Have Difficulty with Traditional Learning Methods* (Ludwig 1993), uses exercises based on drawings of the four “Feelings Faces” to express “happy, sad, mad and scared.” These faces can be used to communicate feelings about various touches (appropriate and not appropriate). O’Day (1983) created a sexual abuse prevention curriculum for use with students with a variety of physical and developmental disabilities. The curriculum includes a list of teaching guidelines, lesson plans (instructions, exercises, handouts, teacher guides), and notes for how to adapt the curriculum for various student impairments. Lessons cover personal safety and myths/facts about sexual assault. Plummer’s (1997) curriculum, *Preventing Sexual Abuse*, provides tips for working with youth with developmental disabilities. She suggests keeping concepts simple and staying within the limits of abilities and attention spans of the youth. Plummer emphasizes repetition to reinforce the learning, as well as utilizing movement, for example, with role plays or cooperative games. Techniques that will be particularly useful with children with developmental disabilities, including ASD, are instruction that is active and participatory, not lecture. Role play and

dramatization are excellent techniques for educating and assessing learning. Reviews have consistently concluded that programs that incorporate modelling (i.e., demonstrating the skill to be learned) and rehearsal (e.g., role plays) are more effective than programs that primarily rely on individual study or passive exposure (Topping and Barron 2009; Walsh et al. 2015; Wurtele 2009; Wurtele and Kenny 2010; Zwi et al. 2007). Given that most parents reported that their children with ASD were usually or sometimes able to follow rules and one- to three-step directions, personal safety training could incorporate simple rules about behavior and touching (Kenny et al. under review).

The program must be simple, use plain language, involve repetition, and be implemented over a lengthy period of time to be as effective as possible. Other strategies include focusing on the concrete, not the abstract and using role plays to build skills through practice. Plummer (1997) recommends that if the prevention training is conducted in a group setting, keep the groups small, with a preferred one-to-four staff to student ratio. Finally, she states parental and teacher involvement is crucial for additional support and reinforcement of material outside of the sessions. Since repetition and reinforcement are necessary for learning, it is imperative that parents, care takers, and educational staff reinforce appropriate behaviors and review concepts.

In addition to using certain techniques in teaching personal safety skills, improving communication skills for those with disabilities is also an important component (Burke et al. 1998). Burke et al. (1998) recommend teaching the names of private parts to youth so that disclosure of abuse is possible. This is consistent with researchers in the field of CSA prevention (Wurtele and Kenny 2011). Often youth are not taught the correct names for basic anatomy and use terms that are not universally understood. Burke et al. (1998) also recommend teaching youth to trust their feelings by validating, rather than dismissing or minimizing, them. Other components of personal safety include helping the individual to identify enjoyable touches and to recognize what is appropriate touch from various individuals (caregivers,

health professionals, etc.) in different circumstances. An understanding of maintaining personal boundaries and for respecting the boundaries of others is another critical component of prevention planning. Children with ASD should be taught a safety plan (e.g., say “NO” loudly, leave and tell someone) when their boundaries are violated.

Personal safety can be viewed as a beginning step in sexuality education. Parents of children with ASD need guidance on sexuality topics, including sexual abuse prevention, and professional assistance in having these discussions. Professionals involved in the lives of children with ASD need to be open to dialogue about these issues and should likely initiate these discussions with parents. As Breuner et al. (2016) state, developmentally appropriate, evidence-based sexuality education over time provided by pediatricians, educators, other professionals, and parents is necessary to assist youth in making informed, positive, and safe choices about healthy relationships, responsible sexual activity, and their reproductive health. Parental concerns should be addressed as they arise with a child’s changing developmental stages. While parents are often reluctant to have such discussions with their children, they are the best educators for their child and can use the opportunity to infuse their values related to sexuality (e.g., premarital sex, abortion, and contraception).

Sexuality education discussions are imperative in personal safety training, as research has shown that lower levels of sexual knowledge are associated with likelihood of being sexually assaulted (Brown-Lavoie et al. 2014). Ballan (2001) further found that all parents were worried about their children being sexually abused and had talked to them about sexual abuse prevention. Some parents of children with ASD fear that discussing sexual-related topics with their children will increase their sexual interest or behaviors (Brown-Lavoie et al. 2014; Konstantareas and Lunskey 1997), although this seems unsubstantiated by research.

Parents of youth with ASD share many of the same concerns as their counterparts with typically developing children, but research has shown that

they have some additional concerns about sexuality education. In the Ballan (2012) study, parents of children with ASD verbalized a strong desire to communicate with their children about sexuality, but felt they were not adequately prepared to do so. In focus groups with parents of children with ASD, Nichols and Blakeley-Smith (2009) found that they felt unclear about what healthy sexuality could look like for their children. Parents also shared concerns that their children struggle with understanding privacy, boundaries, personal space, and not being able to read social cues. All parents worried that their children could be taken advantage of and possibly raped or sexually assaulted. At the same time, they were not sure how much information to give their child, how long to wait until discussing particular topics, and what strategies to use for teaching. The majority of parents in the Ballan (2001) study stated that they would be comfortable communicating about sexuality with their children with ASD, but they questioned their children's ability to comprehend the information as a barrier to discussions.

There are few prevention or sexuality education programs directed specifically at parents of children with ASD. Nichols and Blakeley-Smith (2009) created a group for parents (8 weeks for 1-h per week) to help them discuss certain sexuality topics with their children with ASD and to increase their comfort and competence for these discussions. Parents reported satisfaction with learning, sharing with other parents, and gaining resources for talking with their children. Corona et al. (2016) provided a sexuality education program for teens with ASD and their parents. The program consisted of six 2-h sessions over a 3-month period. Topics included introducing sexuality, puberty, the human body and maturation, masturbation, privacy, friendship development, interpersonal relationships, dating, sexual activity, personal safety, legal issues, and electronic communication. The program relied on techniques shown to promote learning in individuals with ASD including direct, clear, and specific descriptions of the session's topic. When possible, verbal conversation and prompts were accompanied by visual representations of the

subject matter. Participants were consistently and frequently rewarded for their willingness to participate and their compliance with group rules. When necessary, an assistant used verbal and visual reminders of appropriate behavior (Corona et al. 2016). Parents were in simultaneous sessions, which covered the same topics but were also provided ways to support their child. Parents reported having discussed significantly more sexuality topics with their adolescents following the program and decreased concerns about some of the topics. Meister et al. (1994) conducted a six-session parent group aimed at increasing parents' competence in handling issues of sexuality with their adolescent children with ASD. The program included discussion of sexual development, masturbation, preventing sexual abuse, and talking to one's children about sexuality. Group participants completed measures of parent stress and tracked progress on goals they had set for themselves but results of these assessments were not reported.

In sum, programs that utilize behavioral skills training and incorporate teaching techniques known to be effective with children with ASD appear to be the most promising. Educating parents about CSA and the potential risks to their children, as well as ways they can help to ensure a safe environment is an important first step in prevention. It is imperative that parents, caretakers, and schools join in prevention efforts so that youth with ASD receive repeated instruction over time. Booster sessions for youth can help ensure skills are maintained over time. Developing programs that incorporate exceptional education methods while considering potential cognitive and emotional deficits of youth needs to be achieved. Adapting programs that have been used with adults with disabilities may be appropriate, but must consider the developmental level of the child.

Future Directions

While some work has been done in the area of teaching personal safety for children with ASD,

prevention specialists need to develop empirically supported programs that target this group of vulnerable youth. Teaching personal safety to youth with ASD should be a comprehensive approach that begins at home with parents as teachers, continues formally in school, and includes repeated exposure to safety concepts. In addition to targeted programming, Muccigrosso (1991) recommends parents of children with disabilities begin early in their child's life to teach them independence skills, decision-making, and assertive skills – all of which are general protective factors against sexual abuse and can be honed in later prevention programs.

Best practices for personal safety programs suggest that enlisting parents as their children's teacher is the most effective way to teach such skills. This allows for repeated exposure in a natural environment. Additionally, training for parents is critical to increase their awareness of the problem of sexual abuse in youth. Providing opportunities for parents to role-play discussions with their children will be an important component of programming. For programming to be truly effective, it will need to be more than a onetime event. Successful programs should include school-based curriculum and parental involvement; education to ensure that concepts are reinforced in the natural environment (Muccigrosso 1991). It is recommended that frequent booster training in CSA education and body safety training be provided for individuals with ASD, so as to demonstrate enhanced knowledge and skill development, and ensure a sufficient level of maintenance and generalization (Kenny et al. 2013).

Based on their prevention work with mentally deficient Chinese adolescents, Lee and Tang (1998) make a number of recommendations for future programming. These include expanding the complexity of inappropriate request recognition to include more ambiguous circumstances, as well as an emphasis on a behavioral approach that embodies modeling, behavioral rehearsal, and reinforcement. More specifically, vignettes for behavioral rehearsal could cover settings and

people familiar to the child including teachers, aides, and exceptional education staff. Lee and Tang (1998) also recommend inclusion of general sexuality education for children with ASD.

Sexuality education experts will need to brainstorm strategies to overcome challenges and obstacles in teaching children with ASD. As many experts have stated, sexual education is essential for reducing the risk of sexual abuse among children with disabilities. Teaching children about sexuality in a healthy, appropriate manner is necessary or they may learn about it through abusive, exploitive relationships. Sexuality educators will need to join forces with exceptional education specialists to create curriculum for children with ASD, as well as their families, which considers the range of cognitive and verbal limitations these youth may possess. Unique instructional strategies will need to be developed to ensure appropriate instruction that leads to learning for these populations. Sullivan and Caterino (2008) recommend that educators should be prepared to address sexuality with children with ASD in schools through interventions informed by individuals' levels of cognitive functioning, social skills, and awareness.

There is a need to systematically evaluate existing programs and determine their effectiveness. Empirical evaluation of these programs is imperative to ensure children with ASD are receiving the best, most efficacious programming. Guaranteeing that programs meet certain standards and are accessible to school districts or parents is critical. While a number of programs exist, they may not meet rigorous evaluation standards. Children with ASD are vulnerable to abuse and teaching personal safety should be an educational priority to ensure they live a life free from abuse.

Team Approach

Ed Duncan¹ and Giacomo Vivanti²

¹Children’s Centre, La Trobe University, Melbourne, VIC, Australia

²A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, USA

Definition

Team approach is a model involving a team of professionals with complementary backgrounds and skills working together toward common goals.

This approach is increasingly advocated by scholars and policy makers as a means of assuring quality of outcomes and quality of work environment.

Comprehensive intervention models for individuals with autism spectrum disorder (ASD) require the expertise of professionals from multiple disciplines (e.g., physicians, psychologists, speech and language therapists, occupational therapists, special educators). International guidelines (Department of Children and Families 2003; Committee on Educational Interventions for Children with Autism 2001; Roberts and Prior 2006) highlight the importance of employing a collaborative approach of teamwork in providing effective intervention for ASD. Family involvement is a key component of a collaborative intervention approach, especially for successful infant-toddler interventions.

Three collaborative models exist:

- *Multidisciplinary team*. Professionals work in parallel. Individual therapists perform their assessments, goal planning, and treatment according to discipline-specific tasks and hierarchical lines of authority. There is little overlap between the team members.
- *Interdisciplinary team*. Communication and interdependence between professionals is encouraged, and team members contribute their own professional expertise to establish goals and deliver therapy; however, each

member delivers discipline-specific therapy (e.g., the speech and language therapist in the team is responsible for the language component of the intervention).

- *Transdisciplinary team.* Professionals collaborate to produce a single integrated intervention plan. Team members have or develop skills across a range of different disciplines, as they share and integrate their expertise to formulate and implement mutually agreed goals. A high degree of communication and cooperation among the team members occurs within this model. Each member delivers different aspects of the treatment that might or might not relate to their background (e.g., the speech and language therapist in the team might implement fine motor, cognitive, and language intervention).

Research suggests that the most appropriate team approach to address the needs of individuals with ASD is the transdisciplinary approach (Klin et al. 2005; Roberts and Prior 2005). This approach might also serve the purpose of fostering individual team members' capacity to work in a cohesive and cooperative way, with positive effects on work satisfaction and motivation (Vivanti et al. 2017). Moreover, families feel that compared to other models, a transdisciplinary team is more powerful, less intrusive, and more successful in promoting active participation in the treatment programs (Bell et al. 2009).

Further research in this area is necessary, in order to (1) understand the impact of different teamwork approaches across different settings (e.g., childcare, school, clinical setting); (2) address the challenges involved in coordinating team members, ensuring ongoing communication, organizing training, and providing unitary guidelines; (3) address the issue of establishing and maintaining a single clear line of communication with the family.

Telegraphic Speech

Cheryl Smith Gabig

Department of Speech, Language, and Hearing Sciences, Lehman College/The City University of New York, Bronx, NY, USA

Synonyms

Early multiword utterances; Three-word phrases and sentences

Definition

Telegraphic speech is a concise message characterized by the use of three-word short phrases or sentences made up of main content words such as nouns and verbs and void of function words and grammatical morphemes such as articles (e.g., *the*, *a*), auxiliaries or modals (e.g., *is*, *are*, *can*), prepositions (e.g., *in*, *on*), and tense morphemes (e.g., *-ing*, *-ed*, *-s*). The omission of certain words and grammatical morphemes resembles what is typically seen in a brief telegram, hence the term *telegraphic speech*. Telegraphic speech is seen developmentally when a child moves beyond the two-word, relational stage of language development and begins to express longer, three-word sentences using a finite set of grammatical categories, such as nouns, verbs, and adjectives.

Information regarding language developmental milestones (including the use of telegraphic speech) of children with autism is somewhat lacking. Autism is often diagnosed when a child is 3–4 years old following a history of language delay or regression, and the developmental language milestones of children with autism are most often determined by a retrospective parent report of the presence or absence of language behaviors during infancy, toddler, and preschool years.

There are few longitudinal studies of language development in verbal children with autism, although there is some evidence that, when verbal, development of sentence structure is similar to that of typically developing children.

Telehealth: An Effective Model for Providing Behavior Analytic Interventions to Individuals with ASD

Katerina Dounavi¹, Emma Craig² and Jenny Ferguson¹

²Queen's University Belfast, Belfast, UK

Definition

Telehealth involves the use of technology for the delivery of health-related services. It encompasses

the use of computers, mobile phones, and other digital devices for the communication between an expert and a service-recipient. Technological strategies involve the use of computer-based video conferencing, online teaching platforms, live coaching, and related content (Bearss et al. 2017).

Historical Background

Interventions based on applied behavior analysis (ABA) are considered evidence-based practice for individuals with autism spectrum disorder (ASD) and their families (Reichow et al. 2018). Recent studies have proven that access to ABA-based interventions early enough during child development can lead to optimal outcomes (Orinstein et al. 2014).

Albeit this need for highly qualified professionals who can deliver effective interventions to individuals with ASD, the availability of coaching for their caregivers and university-based education in behavior analysis for early-career professionals is scarce. This has resulted in an insufficient number of professionals being credentialed as Board Certified Behavior Analysts (BCBA[®]) and a consequent gap in service provision for individuals with ASD. With autism prevalence now standing at 1 in 59 newborns in the USA (Centers for Disease Control and Prevention 2018) and a total of 70,000 individuals living with autism in the UK (National Autistic Society 2019), the need for BCBAs to reach under-served populations is more pressing than ever before. To illustrate the magnitude of this lack of quality provision with exact numbers, only 376 BCBAs are found in the UK (BACB 2019), translated to a ratio of 1 BCBA per 186 individuals with ASD. With this panorama, it is not surprising that high burnout rates have been reported among early-career BCBAs (Dounavi et al. 2019) with obvious negative consequences of such phenomenon to the quality of services offered and the well-being of individuals with ASD and their caregivers (Weiss et al. 2014). The effects of such shortage are felt strongly in rural areas, where lack of service availability has led to reduced parental satisfaction (Murphy and Ruble 2012).

By exploring new delivery models, researchers can investigate how best to disseminate good training practices and support as many individuals as possible. One model which has the potential to increase the reach of behavior analysis is telehealth, a method already showing promise in studies assessing its effectiveness for the provision of medical treatment for numerous conditions, including diabetes, heart disease, and depression (Department of Health 2011).

Current Knowledge

To date there have been 28 published studies which have solely utilized a telehealth platform to provide behavior analytic services to individuals with ASD (Ferguson et al. 2018). These have demonstrated favorable outcomes and shown the flexibility and efficiency of telehealth across participants, settings, and interventions.

Telehealth can adopt a two-pronged approach to training, adapting proven face-to-face techniques onto the telehealth model. The first approach includes an initial training phase that utilizes technology to provide trainees with the theoretical knowledge on a chosen topic. This usually incorporates established training strategies, such as modeling, role-play, and feedback. Preliminary training has been recognized as a key component in achieving procedural fidelity in behavior analytic interventions (Symes et al. 2006), and telehealth may be the ideal platform for delivering this training in a convenient and cost-effective manner, with a greater level of flexibility than traditional models.

The second approach employed is live coaching. Coaching can be defined as the provision of individualized training and feedback on the implementation of the intervention of choice; it can be conducted via telephone, email, or video-conferencing. Feedback can be provided live or retrospectively via recorded footage. Again, known face-to-face training strategies can be successfully incorporated into a telehealth coaching session including modeling of appropriate behavior, self-monitoring, error correction, behavior skills training, and behavior-specific feedback.

Training packages have most commonly incorporated a combination of initial online training and coaching techniques in a “hybrid” approach (e.g., Simacek et al. 2017).

The technology used in telehealth-based training can be easy to obtain. Video-conferencing software used to conduct didactic training and video coaching is often free to access and readily available (e.g., Skype, Viber, Google Hangouts, or iChat). Hardware such as personal computers, web cameras, or tablets are often already found in the intervention settings. When devices or software are purchased, these are in-expensive and readily available. An important consideration when adopting a telehealth-based approach to training is to ensure compliance with data protection regulations, which vary dependent on region and should be used to guide the selection of appropriate tools (see the Healthcare Insurance Portability and Accountability Act, HIPAA, established in 1996 in the USA or the General Data Protection Regulation, GDPR, enforced in Europe in 2018). Compliance with these regulations is an ethical and legal necessity, and professionals considering incorporating a telehealth component should work to ensure they use technology compliant with the regulations of their region in terms of the security, privacy, and management of data (Hall and McGraw 2014).

The telehealth model has the ability to successfully train a variety of participants employed across different sectors, including schools, hospitals, and family homes (e.g., Ingersoll et al. 2016). The potential of telehealth to bring together multidisciplinary teams mirrors the reality of on-site ASD services where interdisciplinary teams work together to plan provision (Department of Education Department of Health 2015; Dillenburger et al. 2014). In fact, telehealth can be a valuable tool in introducing expertise that would otherwise be unavailable. With that being said, the use of telehealth to train participants other than parents is somewhat limited and further research in this area is warranted.

Providing parents with training to carry out interventions has been researched more extensively and results have indicated this can be done to a high degree of fidelity, translating

parent-mediated interventions as evidence-based practice (EBP) (Wong et al. 2014). Parent training has been highlighted as an essential component of a successful ASD intervention (National Research Council 2001). Using telehealth for parent training has the additional bonus of training being conducted in ecologically relevant settings, i.e., both the parents and the child are being taught skills directly in the environment where they will be most beneficial if used. Additionally, given young age at the start of intervention is a crucial predictor of success (Perry et al. 2011), telehealth is an excellent manner of bringing science in family homes before children have even attended their first educational setting. In fact, existing research on the use of telehealth has primarily been conducted with participants under 6 years old confirming positive outcomes (Ferguson et al. 2018).

A telehealth training model has been used effectively across several ABA-based strategies, displaying the flexibility of the approach. The most common use of the platform has been to determine the function of behavior deemed challenging by utilizing functional behavior assessments (FBA) to determine why the behavior may be occurring or what the individual is communicating when they exhibit this behavior. Once a function has been identified, telehealth can be used to train parents or professionals strategies to teach an appropriate replacement behavior which will allow the individual to access the same outcome in a socially acceptable manner, a process called functional communication training (FCT) (e.g., Simacek et al. 2017). For the most part, functional behavior assessment and functional communication training conducted through telehealth have been successful resulting in the reduction of the behavior considered challenging. Useful analysis of telehealth interventions which were not successful at decreasing the targeted behavior have indicated that failures occurred due to low procedural fidelity displayed by trainees or due to an evolution in the behavior function (Schieltz et al. 2018).

The effectiveness of telehealth has also been demonstrated with naturalistic behavioral interventions and strategies, including Naturalistic

Developmental Behavioral Interventions (NDBI) and incidental teaching (e.g., Neely et al. 2016). These interventions focus on child-directed activities using the participant's motivation in the natural environment to promote and create learning opportunities. They aim to increase communication, imitation, and play skills and enhance the interactions between adult and child. Findings indicate positive outcomes in terms of upskilling parents and professionals. Trainees have been taught ways to play and interact with their child and have demonstrated an ability to use and create teachable moments to a high level of fidelity. The outcomes for the children have been more mixed, with some children making great gains and others less significant. However, this variability again could be dependent on the ability to train to high fidelity (Barkaia et al. 2017).

In order for telehealth to be deemed an EBP, enough high-quality empirical evidence needs to be accumulated (Reichow et al. 2008). When considering existing evidence for the use of telehealth, desired quality indicators are not met. However, as studies primarily score low due to omissions in reporting as opposed to severe methodological flaws, it would be nonsensical to dismiss past research and not embrace the potential of a telehealth as a promising model for the delivery of established behavior interventions (see Ferguson et al. 2018 for a detailed review).

Future Directions

The use of telehealth as a model for the delivery of behavioral interventions and training is promising, although more quality research needs to be undertaken. The existing body of research indicates that this model can successfully be used to train interventionists; however, there needs to be more research to ensure that existing data cover the breadth of behavior analytic strategies and result in best child outcomes. For example, there is scarce evidence on the effectiveness of Discrete Trial Teaching when interventions or parents are trained through telehealth or on the use of telehealth to promote the acquisition of functional living skills.

Greater awareness and adherence to research quality measures will ensure evidence is robust enough to provide an overall designation of telehealth as an EBP. In addition, follow-up data are missing from the majority of published studies; therefore, a more longitudinal perspective is required in order to increase our confidence in claiming that telehealth-based training can be used to create long-term, meaningful changes in behavior.

As previously described, existing research has primarily focused on FBA and associated FCT or naturalistic interventions. Training in other behavior analytic strategies has not been widely researched; in particular, there is a dearth of evidence focusing on using telehealth to support comprehensive ABA provision, where a number of programs are introduced simultaneously to teach skills across developmental domains in an individualized "packaged" intervention. Comprehensive packages such as "Early Intensive Behavioral Interventions" (EIBI) have a strong evidence base (Reichow 2012) and are often the most common form of behavior analytic provision. Although FBA, FCT, and naturalistic interventions can constitute effective components of EIBI, future research focusing on the combination of strategies would test the potential of telehealth to facilitate intensive training and supervision. Despite individual differences in intervention outcome success, varied results have often been dependent on procedural fidelity. Research has aimed to identify factors which may predict success (Ingersoll et al. 2016), but further research is needed in this area.

Similar limitations are also apparent when examining the age range of participants in prior research, with the majority of past studies focusing on children under the age of six. ABA-based interventions can have great success with both a teenage and adult age cohort (Santiago et al. 2016) and future research focusing on telehealth applications with older students would increase the reach of this model.

In sum, the use of a telehealth for the provision of training and ongoing support to parents or professionals has shown to be both feasible and effective. Those wishing to utilize telehealth training

in their practice or conduct research on its effectiveness should do so with recognition to its limitations but more importantly by making improvements in research rigor that will increase our confidence that telehealth is an EBP. Overall, telehealth should be seen as a promising development in the evolution of ABA provision that is in line with wider changes in social interactions in the twenty-first century.

Temper Tantrum

Aaron Stabel

The M.I.N.D. Institute, University of California
Davis Medical Center, Sacramento, CA, USA

Synonyms

Tantrum

Definition

The term “temper tantrum” or “tantrum” refers to a set of disruptive, undesirable behaviors and

emotional distress in response to unmet wants or needs. Typical behaviors that often comprise a tantrum episode include: crying, screaming, yelling, falling to the floor, hitting, kicking, throwing objects, destroying property, and/or self-injury. Temper tantrums are natural during early childhood development (Kaneshiro 2007). While tantrum behaviors usually decrease in frequency, duration, and intensity for most children, chronic, prolonged, and severe tantrum behaviors can be a serious problem with many children in the Autism Spectrum (Schreibman 2005). These problem behaviors contribute greatly to the challenges and stress faced by parents and schools and pose a significant barrier to effective social and educational development (National Research Council 2001).

Tantrums are often related to deficits in communication and serve as an alternative form of request. Functional behavior assessments are used to determine what causes and maintains a problem behavior like temper tantrum. Common causes or functions of tantrum behavior include gaining the attention of another person, gaining access to preferred items or activities, and avoiding non-preferred activities or settings. For individuals with autism, tantrums may be triggered by idiosyncratic and seemingly benign events such as changes in routine, sensory aversions, or violations of ritual or compulsion (Schreibman 2005). The likelihood of a tantrum may be increased by other factors such as lack of sleep, illness, hunger, or other physiological factors. Once the causes of tantrum have been identified, decreasing tantrum behaviors often involves teaching appropriate communication strategies to request (i.e., functional communication training), strategies to prevent the likelihood of tantrum (i.e., antecedent-based interventions), self-regulation training (i.e., self-management interventions), and extinction procedures. Psychopharmacological treatments have also been shown effective in reducing tantrums and associated problem behaviors in children with autism and related disorders (Portes et al. 2003).

behavioral characteristics (Henderson and Wachs 2007). Differences exist in the latency, intensity, and threshold of children's reactions to their environments as well as in the ability to maintain or regain a state of equilibrium using self-regulatory processes, such as effortful control (Rothbart and Derryberry 1981). As a group, children with autism are characterized by lower levels of extraversion and positive affect, higher levels of negative affect, and more difficulty regulating attention and emotion based on both parent- (De Pauw et al. 2011; Konstantareas and Stewart 2006) and self-reported assessments (Schwartz et al. 2009). The infant siblings of children with autism (ASD-Sibs) display a distinct profile of temperament compared to the infant siblings of typically developing children that is characterized by lower levels of positive affect, higher levels of negative affect, and difficulty controlling attention and behavior. ASD-Sibs who go on to receive a diagnosis themselves are further characterized by low levels of behavioral approach, or sensitivity to social rewards (Garon et al. 2009). These findings demonstrate both concurrent and predictive associations between temperament and ASD.

Importantly, there is just as much heterogeneity in mean levels and profiles of temperament among children with autism as there is for typically developing children. Several studies suggest that temperament may be an important predictor of individual differences in symptom presentation, adaptive functioning, and comorbid psychopathology. For example, among children with ASD, those with more symptoms are rated by parents as being lower in effortful control (Konstantareas and Stewart 2006), lower in surgency, and higher in negative affect (De Pauw et al. 2011). Similarly, in a sample of higher functioning children and adolescents with autism (HFA) and a typically developing comparison sample, Schwartz et al. (2009) found that children with HFA were rated by their parents as having more internalizing problems. However, over and above this effect of diagnostic group, lower self-reported surgency was associated with higher parent-reported internalizing problems for both TD and HFA participants. Similarly, after

Definition

Temperament describes early appearing, biologically based, and relatively stable individual differences in physiological, emotional, and

controlling for the effects of diagnostic group, higher levels of self-reported effortful control were associated with fewer externalizing problems for both TD and HFA participants. Together, these findings suggest that temperament may provide important additional information related to symptom presentation and comorbid behavioral and emotional problems in children with autism. In addition, given comparable patterns of associations with important adjustment outcomes for children with ASD and typically developing children, the mechanisms linking temperament to adjustment are comparable regardless of diagnostic status (De Pauw et al. 2011; Schwartz et al. 2009).

Given the inherent methodological challenges of relying exclusively on parent- and/or self-reported measures of temperament (i.e., reporter biases), it is suggested that multimethod assessment approaches be employed that incorporate multiple informants' perspectives and include direct observational assessments of temperament. A better understanding of individual differences in temperament is important for identifying early risk factors and better tailoring prevention and early intervention efforts to fit the individual needs of children with autism.

Temperament and Atypical Behavior Scale Screener (TABS Screener)

Laudan B. Jahromi and Crystal I. Bryce
School of Social and Family Dynamics, Arizona
State University, Tempe, AZ, USA

Synonyms

[TABS](#); [TABS screener](#)

Description

The Temperament and Atypical Behavior Scale (TABS) is a norm-referenced assessment of developmentally dysfunctional behavior or behavior problems for infants and children aged 11–71 months (Neisworth et al. 1999). The purpose of the TABS is to identify children with atypical development or those at risk for atypical development in order to allow for early intervention planning. The TABS contains two components: the TABS Screener and the TABS Assessment Tool. The TABS Screener is a brief 15-item questionnaire that can be completed in approximately 5 min and is used to determine if a child requires a more thorough assessment of developmental aspects related to temperament and self-regulation. The TABS Assessment Tool

contains 55 questions about the child's behavior that can be completed in approximately 15 min. Both the Screener and Assessment Tool should be completed by a parent or professional who is familiar with the child's daily behavior (Neisworth et al. 1999). A "yes" on this measure indicates that the behavior is a current or recent problem, and a "no" indicates that the behavior is not a problem or does not apply to the child. Some of the questions require a subjective judgment of frequency, duration, or intensity of behaviors.

The questions from the TABS Assessment Tool load onto four factors: detached, hypersensitive/active, underreactive, and dysregulated. Behaviors consistent with the detached factor include such things as being withdrawn, unengaged, or disconnected from everyday life that involves other individuals. These behaviors may often be seen in individuals with autism spectrum disorder. The second factor, hypersensitive/active, reflects overreactive, impulsive, and highly active behaviors. Often these behaviors are associated with attention-deficit/hyperactivity disorder (ADHD). The third factor, underreactive, refers to behavior that is often unresponsive and requires intense stimuli to elicit a response from the child. The fourth factor, dysregulated, contains behaviors that indicate the child has trouble controlling behavior that has a neurological basis, and may have trouble sleeping and hypersensitivity to contact. Overall, the four factors are used to determine if a child's temperament and self-regulation are atypical (Neisworth et al. 1999, p. 3).

Historical Background

The TABS Assessment Tool was based on more than 10 years of research by its authors on the temperament and self-regulatory styles associated with developmental delay. The authors of this measure aimed to overcome many of the conceptual and methodological limitations of applying commonly used adult measures of behavior problems and psychopathology to infants and young children. The goal of this measure is to detect early behavior problems and to help practitioners

to devise an intervention plan for young children. The scale is based on research in the areas of typical self-regulation development, characteristics of atypical self-regulatory development, and specific self-regulatory problems associated with diagnosed neurodevelopmental/neurobehavioral disorders (Neisworth et al. 1999, p. 7). The TABS authors define temperament as a biologically based behavioral style that influences dimensions of behavior and self-regulation. More specifically, self-regulation is the ability to control and monitor behaviors according to social demands. The measure identifies unusual temperamental and self-regulatory behaviors, or indicators, that have been previously associated with neurodevelopmental disabilities, such as autism spectrum disorder, with items that focus on neurobehavioral markers, or early atypical behavioral patterns thought to have a neurological basis (Neisworth et al.).

Psychometric Data

The scores derived from TABS reflect overall self-regulatory problems, with higher raw scores indicating more atypical self-regulation. Calculating the Temperament and Regulatory Index (TRI) from the TABS Assessment Tool allows for interpretation of raw scores. The authors suggest that using TABS normative cutoffs, a TRI score of 5 indicates at-risk status and a TRI of 8 or higher is indicative of severe behavioral dysfunction.

The TABS normative sample consisted of 621 children (11–71 months of age), 52% of whom were 2 years old or younger. Approximately 60% of the sample's gender was not identified. The scores of children with disabilities in this sample were compared to the scores of children without disabilities; children with disabilities consistently scored higher, indicating poorer performance (Neisworth et al. 1999).

The internal consistency of the TABS Assessment Tool was determined using a split-half reliability procedure, which divided each subtest in half and then correlated the halves of each subtest. The reliability coefficients for children not at risk, for children with disabilities, and for the pooled

sample were .88, .95, and .95, respectively (Neisworth et al. 1999). The authors do not recommend using TABS subtest profiles for diagnostic purposes, as some of the subtests have insufficient reliability for this purpose. Internal consistency of the TABS Screener was determined using coefficient alpha, yielding an alpha of .83 (Neisworth et al. 1999).

With respect to the validity of the TABS Assessment Tool, the authors report that the measure shows a factor structure consistent with theoretical models proposed by Zero To Three: National Center for Infants, Toddler, and Families in 1994. With respect to accuracy of the TABS Screener, about 72% of the children who are screened as at risk or as having a disability will have been screened accurately (Neisworth et al. 1999).

Clinical Uses

The scores derived from TABS may allow clinicians to identify those children who may have a need for early intervention, to assess children's behaviors before the start of intervention, and to help therapists monitor and evaluate progress over the course of intervention. The scores derived from TABS can be used by state agencies as a standardized criteria necessary for families to meet eligibility for government-funded intervention programs or wraparound support (i.e., services that lend support to the family and the child) (Neisworth et al. 1999).

Child Study Center, Yale University School of
Medicine, New Haven, CT, USA

Synonyms

[Temporal cortex](#)

Definition

The temporal lobes are bilateral portions of the cerebral cortex. They are demarcated at the top by the Sylvian fissure and extend to the ventral (lower) most surface on the brain. The temporal lobes are involved in a variety of key cognitive functions. For instance, they are home to auditory cortex (responsible for the perception and processing of sound). Moreover, portions of the temporal lobes are responsible for high-level semantic processing in language, recognition of letters and words, and processing faces and other complex objects. The medial temporal lobes, especially the hippocampus, also play a key role in the formation and retrieval of long-term memories. Wernicke's area, which spans the region between temporal and parietal lobes, plays a key role (in tandem with Broca's area, which is in the frontal lobe) in language.

Test Bias

Michele Goyette-Ewing
Yale Child Study Center, New Haven, CT, USA

Definition

Test bias refers to the systematic under- or over-prediction of a particular trait or status based upon one's group membership. Groups may include individuals of different races, ethnicities, genders, and socioeconomic statuses. A test may be considered biased because it was not developed using a standardization sample that is representative of the populations on which it is used. According to Sattler and Hoge (2006),

procedures for evaluating assessment instruments for test bias include: (1) examining content for evidence of cultural bias, (2) examining construct validity to determine whether the test measures the same constructs or behavioral dimensions for different groups, and (3) examining criterion-related validity, for example, by determining whether a measure significantly predicted success in treatment for one group but not another. Ortiz and Dynda (2005) argue that, when considering the cultural fairness of a test, test bias is a limited construct as it conflates race and ethnicity in the construction of norm groups and evaluation of a test's psychometric properties. They suggest that when considering tests used with individuals from culturally and linguistically diverse groups, the validity of the test is dependent upon the extent to which evaluation methods and procedures used were appropriate and successful in accounting for the known influence of culture and language on test performance during the evaluation.

Test for Auditory Comprehension of Language – Fourth Edition

Sara Beltran, Jordan Lee and Ania Spina
Southern Connecticut State University,
New Haven, CT, USA

Synonyms

TACL-4

Description

The TACL-4 measures language in the areas of syntax and semantics for children ages 3–12 (three sets of stimuli for ages 3–5, 6–10, and 11–12). The test aims to establish what areas of language comprehension are challenging for children (Brown 1986). Three subtests make up the TACL and include test vocabulary, grammatical morphemes, and elaborated phrases and sentences. The length of administrations is between 15 and 20 min. The TACL-4 includes basals and ceilings to reduce frustration in testing and to reduce the time needed to administer the test. This test is appropriate for use by speech-language pathologists, educational diagnosticians, and professionals in related fields, requiring some formal training in assessment.

As a receptive assessment, the test uses visual stimuli presented in a standing flip book. Selection of answers from three picture choices is performed by pointing with no verbal expressive language required. The pictures are realistic, hand-drawn, color pictures of items, avoiding biases (such as race, sex, age, socioeconomic) where possible. The arrangement of correct images is distributed equally in left, middle, and right positions. Instructions for use of the test are clear and easy to administer. Administration uses the same phrase “Show me” throughout the test. Scoring uses 1 for correct and 0 for incorrect (or no response). Correct answers are indicated on the score sheet as A, B, or C for position on page.

Scoring for the TACL-4 uses age equivalents, percentile ranks, scaled scores with a mean of 10 and standard deviation of 3, and a receptive language index (composite score) with a mean of 100 and standard deviation of 15. These measures can support qualification for language services for children who fall below the norms. The TACL-4 is co-normed with the Test of Expressive Language, both of which are designed to be used with children of all abilities (TEXL; Carrow-Woolfolk and Allen 2014). Both assessments are intended to produce cross-battery measures of linguistic systems, characteristics, and general oral language (Carrow-Woolfolk 2014). Comprehensive Scoring Supplement is available to allow comparison of scores and/or combining of scores to produce a more comprehensive measure of a child’s language ability.

Historical Background

The original version of the TACL came about in the early 1960s by Elizabeth Woolfolk (Carrow-Woolfolk 2014). Woolfolk’s inspiration came from an interaction with a 3-year-old boy, who was unable to comprehend or respond to spoken language, maintain eye contact, and struggled with anger outbursts. Woolfolk studied the word categories and patterns they followed. The creation of the TACL was an attempt to identify issues in using these categories and patterns and a means to promote earlier intervention for future clients in similar situations. The initial focus was to evaluate the morphological, syntactical, and lexical components of language because this combination is missing from other receptive language measures (Blood and Greenberg 1978). Background research for the original TACL was based on 40 children, and the results were used to assist with item revision, presentation, order, etc. Once a model assessment was complete, it was used on 159 students (ages 2;10-7;9), controlled for similar IQ, no hearing or speech issues, and monolingual. Over the span of the next decade, the second and third versions of the TACL were released, but it wasn’t until 2013 that the TACL-4 was released. This update was

important because the data collected was from a more diverse demographic. Additionally, the TACL-4 age range is expanded to include 10;0–12;11 and requires less time to administer, and the floor and ceiling effects are greatly reduced in comparison to previous versions.

Psychometric Data

Standardization of the TACL-4 was determined by a sample size of 1,142 children with ages ranging from 3 years, 0 month to 12 years, and 11 months. The normative sample's characteristics were nationally representative for school-age population based on the characteristic's comparable percentages of those in the *Statistical Abstracts of the United States 2013*. The pictures chosen for the test have been designed to be as unbiased as possible, with an equal representation of all demographics throughout the assessment.

Reliability looked at the assessments subtests and the assessment as a whole. Reliability coefficients for content sampling and inter-scorer differences were all above 0.95. Time sampling's highest coefficient was 0.85 for receptive language index and lowest coefficient was 0.71 for grammatical morphemes. These scores indicate high reliability in the TACL-4.

Assessment of criterion-predictive validity was determined by comparing the TACL-4 with three similar assessments: Clinical Evaluation of Language Fundamentals-Fourth Edition (CELF-4; Semel et al. 2003), Clinical Evaluation of Language Fundamentals Preschool-Second Edition (CELF Preschool-2; Wiig et al. 2004), Oral and Written Language Scales-Second Edition (OWLS-II; Carrow-Woolfolk 2011), Diagnostic Achievement Battery-Fourth Edition (DAB-4; Newcomer, 2014), and Test of Expressive Language (TEXL; Carrow-Woolfolk and Allen 2014). The receptive, expressive and general language of the 3 assessments were compared to the TACL-4 by computing each assessment's language measures, means, standard deviation, and diagnostic accuracy. The correlation between all tests and measures of each test was at a magnitude between large and very large, meaning the

coefficients fell in a range between 0.70 and 1.00, with receptive language being the strongest of measures and supporting the TACL-4 as accurately testing areas of oral language. Additionally, TACL-4 standard scores will be similar to the scores from assessments of oral language based on means and standard deviation effect sizes which were small to trivial for receptive language tests and trivial to moderate for expressive and general language. For diagnostic accuracy, the specificity index results for each assessment reveal that the TACL-4 has high accuracy when predicting similar scores of receptive language assessments than assessments that looked at expressive and general language. The high accuracy gives strong validity in the TACL-4 in predicting children who do and do not have a language impairment.

Construct identification validity was measured based on various components. Relationship to age was strongly correlated, obtaining a magnitude of very large correlation with coefficients ranging from 0.73 to 0.76 for each subtest. Relationship to academic achievement was assessed comparing six achievement tests that assessed different literacy skills. The correlation coefficients compared to the various assessments ranged from 0.5 to 0.76, showing that the assessments all tested related, but different abilities indicating a relationship between the TACL-4 and achievement. The relationship to intelligence was revealed through comparison to various intelligence tests. The scores between the Abbreviated Battery Review of the Stanford-Binet Intelligence Scales-Fifth Edition (SB5 ABIQ; Roid 2003) and the Brief Intellectual Ability section from the WJ III assessments and the TACL-4 revealed coefficient scores ranging from 0.58 to 0.82, indicating high support for construct identification validity for each subtest. Subtest interrelationship coefficients for each subtest ranged from 0.42 to 0.49, indicating that the subtests all assess individual aspects of Auditory Comprehension. The validity coefficients indicate that the TACL-4 is a valid assessment for oral language comprehension. A review search of the TACL-4 did not reveal any recent articles since the TACL-4 revision.

Clinical Uses

The TACL-4 tests a child's receptive language in the domains of spoken vocabulary, grammar, and syntax. It is well-suited for use with English-speaking children in schools in the United States. Past research has also concluded that the use of the TACL is successful in measuring the receptive language age of children with intellectual disabilities (Beisler and Tsai 1987). There are also significant associations between a child's language comprehension and executive functioning skills (Lyberg-Åhlander et al. 2015). The TACL-4 would be best suited for a child who achieves low scores in the reception section of a broader assessment. The clinician can then use the scores of the TACL-4 to further refine understanding of areas of challenge and develop a specific intervention for the child. This tool is beneficial to assess receptive language for a child who is nonverbal due to a physical disability.

Test of Early Language Development (TELD)

Aparna Nadig
School of Communication Sciences and Disorders, McGill University, Montreal, QC, Canada

Synonyms

TELD; TELD-2; TELD-3

Description

The Test of Early Language-3rd edition (TELD-3) is a test developed for the assessment of the comprehension and production of English spoken language (focusing on syntax and semantics) in children aged 2;0 to 7;11 years, toddlers to second grade students. Not to be confused with the Test of Language Development (TOLD), now in its 4th edition, for the assessment of oral language in 4;0 to 17;11 year-olds (in primary and intermediate versions). Newcomer and Hammill. Test of Language Development, Fourth Edition (TOLD-4), Western Psychological Association.

Test format and scoring (as reported in Backlund, Morreale, and Suen 2001):

The TELD-3 is to be administered individually. It contains two forms, (A and B). Each form has two subtests, one for Expressive Language

and one for Receptive Language. The Receptive Language subtest contains 37 items; Form A has 24 semantic items and 13 syntax items, while Form B has 25 semantic items and 12 syntax items. The Expressive Language subtest contains 39 items; Form A has 22 semantic items and 17 syntax items, while form B has 24 semantic items and 15 syntax items.

The test materials are easy to use and well prepared. For each item, the child is given a verbal direction and then shown a stimulus object or a picture. Then the child is invited to respond to prompts for each item. This response is scored by the examiner.

The 3rd edition yields an Overall Spoken Language score as well as separate Receptive and Expressive Language subscores. Standard scores (mean of 100 and standard deviation of 15), percentiles, and age equivalents are provided for subtests and for a composite score.

Normative information is reported with respect to geographical residence, gender, race, ethnicity, education, and socioeconomic status, and is stratified by age. Color pictures and manipulatives are included in the test kit. Testing time is reported to take 15–45 min.

Applications in Research on Autism Spectrum Disorders

Although the TELD appears often in the typical language development, stuttering and specific language impairment literatures, as of 2011 it has yet to be applied widely in Autism Spectrum Disorder (ASD) research. Potential uses are for characterizing profile of functioning, matching between comparison groups in experimental studies, and identifying language impairment.

Waterhouse et al. (1996) employed the first edition of the TELD to characterize language level in part of their study sample of 194 preschool children suspected of ASD. Their study compared four systems for the diagnosis of autism (DSM-III, DSM-III-R, DSM-IV, and ICD-IO) and sought to quantitatively identify subgroups of children with pervasive developmental disorder. Their results identified lower- and higher-functioning subgroups with considerable overlap,

suggesting a continuum of pervasive developmental disorders.

Koegel, Carter, and Koegel (2003) used the first edition of the TELD for initial characterization of two children with ASD in a multiple-baseline intervention study focused on increasing the use of grammatical morphemes.

Herbert and colleagues (2003, 2004) have conducted a series of neuroimaging studies examining increased cerebral white matter volume in children with Developmental Language Disorder and High Functioning ASD, relative to typically developing children. All participants had Performance IQs greater than 80. Characterization of language in potential participants with non-ASD Developmental Language Disorder was done using the TELD (first edition) as well as mean length of utterance. Inclusion in the Developmental Language Disorder group required scores that fell one standard deviation or lower below the mean on the TELD. Similar language characterization was unfortunately not conducted for the ASD group. Herbert et al. highlight a similar distribution of white matter enlargement in both clinical groups, and raise the possibility that they fall along the same spectrum. However, this comparison needs to be examined in a sample where the language ability of all participants is characterized, to understand the relationship between anatomical changes and behavior. Overlap and differences in white matter volume profiles between the two clinical groups warrant further study.

Applications in Research on Theory of Mind and Language Development

In contrast, the TELD has been used extensively with typically developing children, especially in research focusing on the relationship between language and theory of mind abilities. This practice likely has its roots in Astington and Jenkins (1999) seminal article on the developmental relationship between language and theory of mind, where they used the TELD to assess language skills three times over a 7-month period in 3-year-olds. They report that earlier language abilities predicted later theory-of-mind performance (controlling for earlier theory of mind), but not the

reverse. Subsequently, the same measure was used in number of other studies on related topics (Cassidy et al. 2005; Cheung et al. 2004; Farrar et al. 2009; Ng et al. 2010).

Historical Background

The Test of Early Language Development was developed around two of three central features of language identified by Bloom and Lahey (1978): content (knowledge of objects, relationships among objects and events - semantics and reference) and form (phonology, syntax, morphology). Language use, the third feature, was not incorporated in the assessment. It was designed to be a quick and easy-to-administer screener of spoken language for young children.

The first edition of the TELD was published in 1986 for use with children aged 3;0 to 7;11. The standardization sample included 1,184 “typical” students who are comparable, where possible, to a US national sample with respect to demographic characteristics.

The second edition, TELD-2, was published in 1991. It provided one overall spoken language score with no subscales. Sorensen and Bradley-Johnson (1993) noted a lack of test-retest reliability by age group as a concern for this edition. The standardization sample included 1,329 students approximating the 1990 US census with respect to demographic characteristics; 150 children were included per age group.

The third edition (TELD-3) was published in 1999. It is designed to assess English spoken language skills at early ages (from 2;0 to 7;11). The TELD-3 has two subtests, Receptive Language and Expressive Language, and yields an overall Spoken Language score. This edition addressed previous criticisms by division of items into Receptive Language and Expressive Language scales, development of standard scores, more effective coverage for children at the upper and lower age ranges of ability, new studies supporting reliability and validity, increased normative data, more visually appealing, color pictures, more accurate wording, and

clearer instructions for test administration (Backlund et al. 2001). This edition includes all necessary manipulatives in the test kit, unlike previous versions.

The TELD-3:S is a Spanish translation and adaptation of the TELD:3 that was published in 2007 to assess early Spanish spoken language in the same age range (from 2;0 to 7;11), (Ramos and Ramos 2007).

Psychometric Data

The TELD-3 has high reliability and excellent validity.

Demographics: The TELD-3 was standardized on 2,217 children representing 35 US states. The normative population was representative of the US population as reported in the 1997 *Statistical Abstract of the United States* (U.S. Bureau of the Census 1997). The test website reports that a wide range of both mainstream and minority populations, including gender, racial, ethnic, linguistic, and disability categories, was included in the normative sample.

Limiting bias: The TELD-3 was examined to ensure that little or no bias relative to gender, disability, racial, socioeconomic, or ethnic groups existed. Reliability and validity information is provided for different mainstream and minority subgroups.

Reliability: Adequate test reliability (coefficient alpha, test/retest, immediate test/retest with equivalent forms, and interscorer) was established.

Validity: Content-description validity was established through careful selection of items, controlled vocabulary, construct review by a panel of language experts, conventional item analysis, differential item functioning analysis, and form equivalence.

Criterion-prediction validity was established by correlating TELD-3 standard scores with a variety of widely recognized measures of language ability (i.e., CELF Preschool, EOWPVT, PLS-3, PPVT-Revised, ROWPVT, and TOLDP:3).

Construct-identification validity was established by studying (a) the relationship of

the TELD-3 standardized scores with age, IQ, and academic achievement and (b) the ability of the TELD-3's standard scores to differentiate groups with known language problems from those without such problems.

Clinical Uses

The TELD-3 is used for the spoken language (syntax and semantics) assessment of children aged 2;0 to 7;11 years, toddlers to Grade 2. The authors identify five purposes of the test: to identify candidates for early intervention, to identify strengths and weaknesses of individuals, to document progress in an intervention program, to serve as a research tool in language development, and to accompany other assessment techniques (Hresko et al. 1999).

Though clinical usage as described above does appear to be a potential use of this test, Backlund et al. (2001) caution that the authors did not report any evidence of these applications, such as positive predictive power indices or over- or underreferral indices, to support its use for identification. There is also no evidence in the manual such as treatment validity to support its use to identify strengths and weaknesses or to document progress in intervention. A literature review in June 2011 did not identify any published studies employing the TELD in ASD assessment or as an outcome measure in intervention research.

The TELD-3 does include two different forms (A and B) of items, making it useful for longitudinal and intervention studies where retesting over short periods of time on the same items is often an issue. Its effectiveness in such applications will need to be determined by future research.

Test of Early Language Skill

Maura Moyle and Steven Long
Speech Pathology and Audiology, Marquette
University, Milwaukee, WI, USA

Synonyms

[ELS](#); [ELS checklist](#)

Description

The *Early Language Skills Checklist* (ELS Checklist) is an observation-based assessment for use by preschool teachers and childcare workers for assessing language abilities in children between the ages of 3 and 5. The ELS Checklist consists of 59 items falling under four broad categories: Attention Control and Listening Skills, Receptive Language, Expressive Language, and Use of Language. The authors caution that the ELS Checklist is intended for assessing children whose first language is English and should not be used for making clinical decisions about children who speak English as a second language. The ELS Checklist uses both assessment tasks (i.e., elicitation procedures) and

naturalistic observations that are carried out over the span of 2–3 days within different communicative contexts. Total administration time is approximately 30 min. Items are scored as “yes” or “no” based on whether the child is able to do the task. If a child can perform the most developmentally advanced item within a set, the easier items do not need to be administered. In some cases, skills need to be observed on at least three occasions to ensure mastery before a score of “yes” is given.

Historical Background

The ELS Checklist was developed in Great Britain and designed for monitoring children’s progress in language development according to *Code of Practice on the Identification and Assessment of Special Educational Needs in England and Wales* (1996), and also in line with similar requirements put forth by Scotland and Northern Ireland. Only one edition of the ELS Checklist has been published to date, and it is currently out of print.

Psychometric Data

No psychometric data are provided.

Clinical Uses

The ELS Checklist provides information about general developmental expectations for each item. Teachers can use these guidelines to help identify children who may have significant language delays. Strengths and weaknesses in children’s language development can be identified by comparing results across the four categories assessed. In addition, performance can be compared across settings and communication partners (e.g., group vs. one-on-one interactions). Teachers can record children’s results on the Early Language Skills Profile across multiple administrations to track growth (or lack thereof).

The manual provides guidelines for setting goals and intervention ideas for promoting language development.

Although the ELS Checklist is described as an easy-to-use “observation-based” assessment for use by “nursery or reception staff,” many of the procedures include elicitation methods (e.g., asking the child to identify rhymes or body parts) or carefully engineered small group interactions (e.g., observing the child with two to three peers who are “neither too outspoken nor withdrawn,” while engaged in a specific type of activity). In addition, examiners are required to elicit language samples which are subsequently analyzed for verb tense use and sentence structure. The user manual recommends videotaping the language samples for later scoring. It seems that for most early childhood teachers operating within a typical classroom setting these procedures would not be feasible (e.g., engineering interactions, videotaping language samples). In addition, a high level of expertise in language assessment is needed to elicit the desired behaviors and perform the analyses (e.g., collect a high-quality language sample and identify verb tense use).

The ELS checklist requires that children between the ages of 3 and 5 be able to follow directions and, in many cases, provide verbal responses. Therefore, it may not be appropriate for children with ASD in this age range who are nonverbal and/or exhibit significant developmental delays. In addition, the ELS Checklist is currently out of print. Suitable alternatives for the assessment of language may include:

Test of Early Mathematics Ability-3

Louise Spear-Swerling
 Southern Connecticut State University,
 New Haven, CT, USA

Description

The *Test of Early Mathematics Ability, Third Edition* (TEMA-3, Ginsburg and Baroody 2003), is a standardized, individually administered norm-referenced test of mathematics performance, with norms for children who are 3–8 years old. The test takes about 40 min to administer and is intended to tap both informal and formal mathematics. Informal mathematics involves skills and knowledge typically acquired outside of school, such as counting skills and understanding of relative magnitude (e.g., 7 is more than 3). Formal mathematics involves skills and knowledge that children usually learn in school, such as base ten concepts (e.g., identifying ones, tens, and hundreds in a written numeral) and procedures for adding or subtracting two-digit numbers with regrouping (e.g., calculating the correct answer for $23 + 49$ or $60 - 27$). It should be noted, however, that the test yields only a comprehensive (total) score, not individual subtest scores for different areas of math.

The TEMA-3 provides age equivalents, grade equivalents, percentile ranks, and standard scores that have a mean of 100 and a standard deviation of 15. For interpreting children's performance, standard scores or percentile ranks should be used. There are two forms of the test, A and B, with procedures to equate scores on the two forms

so that they can be used interchangeably (e.g., to pretest and posttest before and after intervention). The third edition of the test comes with a book of assessment probes and instructional activities. Educators can use the assessment probes to further pinpoint individual children's math weaknesses and the instructional activities to improve children's skills in specific math areas.

Psychometric Data

According to information from the test publisher, the standardization sample for the *TEMA-3* comprised 1,219 children with characteristics (breakdown of socioeconomic status, race/ethnicity, etc.) roughly comparable to those in the 2001 U.S. Census. Internal test reliabilities for various age groups are in the .90s, which are excellent; some alternate-form and test-retest reliabilities are a bit lower but still all in the .80s or .90s. The validity of the test as a measure of children's mathematical performance has been established experimentally (Brassard and Boehm 2007; Dumont and Willis 2007). The third edition of the test also includes numerous bias studies demonstrating that the test is not biased in terms of gender or ethnicity.

Clinical Uses

The *TEMA-3* is easy to administer and useful for identifying children ages 3–8 years old who are either mathematically advanced or at risk in mathematics. For this age range, the test could also be helpful as part of a broader comprehensive evaluation for special education, especially for children suspected of disabilities involving mathematics or, conversely, those believed to be mathematically gifted. In addition, the *TEMA-3* can be employed as an indicator of children's overall progress in a math intervention or special education program. Because of the lack of individual subtest scores, the test is somewhat less useful as a detailed math diagnostic measure or indicator of children's progress in specific math skills. However, consideration of specific test items and use

of the assessment probes can provide additional information beyond the overall *TEMA-3* score.

Test of Narrative Language

Barbara A. Cook

Department of Communication Disorders, Center of Excellence on Autism Spectrum Disorders, Southern Connecticut State University, New Haven, CT, USA

Synonyms

[TNL 2](#)

Description

The Test of Narrative Language – Second Edition (TNL-2) is designed to assess the ability of an individual in understanding and relating stories from and to communication partners. Linking to the collective understanding of the development of narrative language and correlation to success in other aspects of communication, such as literacy, the TNL-2 supports the examiner in assessing

comprehension and expression of three types of narratives: scripts, personal narratives, and fictional narratives. The TNL-2 is normed for individuals age 4 years 0 months through 15 years 11 months and includes visual stimuli for six tasks which include a comprehension and production task for each of the three types of narratives. Additionally, with the exception of the script narrative, different topics are presented for the types of narratives. Comprehension questions for the script narrative include five literal and nine inferential questions related specifically to the problem outlined. The personal narrative questions include six literal and six inferential questions regarding the characters, events, and consequences from the story. Last, the fictional narrative questions include four literal and eight inferential regarding characters, events, and consequences, while also focusing on responding to why and how questions, thus requiring perspective and non-literal interpretation. Production requires the individual to verbally express narratives that include key thematic elements, linguistic devices of temporal and causal conjunctions, grammatical accuracy, and character dialogue. Slight variation between the narrative type is the direct retell of the script narrative, creating a story related to the presented pictures that may be familiar, and creating a fictional story that intentionally includes a topic and/or character to ensure lack of familiarity.

The TNL-2 tasks have no basal, ceiling, or time limits. There is indication of an average time of administration falling between 15 and 30 min. Additionally, the authors suggest encouraging examinees to not spend unnecessary time over specific comprehension questions and to expect that most individuals will be capable of planning the oral narrative within 1 min. Digital recording is recommended to assist with scoring.

Scoring of each task for both comprehension and production results in total raw scores which are translated into age equivalent, percentile rank, and scaled scores for a total comprehension and production performance rating. These are then combined to establish a composite performance referred to as the Narrative Language Ability Index, resulting in percentile rank and standard

score. Both the scaled scores for the comprehension and production subtest performance and standard score for the composite are translated into descriptive terms aligning to the following rubric: very poor, poor, below average, average, above average, superior, and very superior. Standard error of measurement are provided to assist with interpretation of the scores. Three areas of observation are recorded to assist in analyzing possible variables that could impact outcomes, including speech production, fluency, and voice. The authors provide additional information regarding potential floor and ceiling effects, indicating no ceiling effects and possibly mild floor effects at the 4-year-old level; thus scores at the lower range for this age group should be interpreted with caution. Lastly, the authors provide information and guidance regarding interpretation of the results and consideration of cultural influences.

Historical Background

Since the 1980s and 1990s, and perhaps earlier, the link between narrative language and cognition, socialization and academic achievement has been expressed in the literature (Mandler 1984; Merritt and Liles 1989; van Dijk 1981; Applebee 1978). Of note is the critical link narratives provide for children between the contextualized language of conversation and the decontextualized language of the classroom, possibly allowing for greater success in an academic setting (Paul et al. 2018). Individuals with language disorders may present with challenges in their use of narration, thus be disadvantaged in achieving success both socially and academically. This is particularly noted in individuals with autism (ASD). Individuals with ASD may evidence microstructure yet lack the macrostructure required to convey a clear and coherent narrative. For example, they may include irrelevant information (Norbury and Bishop 2003).

The challenge presented to the authors was identifying the best approach to assess narrative language that encompasses critical aspects of narration at both the micro- and macro-level while providing a standardized method of comparison to

same age peers. Most standardized instruments assess isolated aspects of language needed for narration and not narration as an outcome. Although there exists agreed upon characteristics of narrative language that include structure, modality, type of narrative, and the development of narrative in children, a measure that was standardized was still needed. Therefore, the authors developed the original TNL to meet this need. The first iteration of the TNL was first published in 2004 and designed to reduce the need of transcribing children's stories. The TNL provided explicit prompts that could ease this process of transcription while providing a standard approach to assessing narration. Based on feedback and current research, the authors began a process of revision in 2012 (Gillam and Pearson 2017). Improvements include new standardization data, larger normative sample, pictures to support all stories, pictures added color and are of higher interest for children, increased number of comprehension questions, scoring for production (oral narratives) is consistent across all, increased data regarding test validity, and diagnostic accuracy.

Psychometric Data

Standardization was established on a normative sample of 1310 children age 4 years 0 months to 15 years 11 months and representative of the United States per comparison of percentages with the ProQuest Statistical Abstract of the United States 2015 and the Digest of Education Statistics 2014 (as cited by Gillam and Pearson 2017). Stratification of selected demographic categories at each age interval further demonstrates normative representation (Gillam and Pearson 2017). Recruited examiners met specific indicated criteria, represented each of four US demographic regions, and were trained in the administration of the assessment.

Overall reliability for the TNL-2 exceeds the desirable level of a coefficient of above 0.80. The authors provide results to three types of correlation coefficients to express test reliability. A Cronbach's (1951) coefficient alpha revealed 0.81 for comprehension subtest, 0.87 for production subtest, and 0.90 for composite of Narrative

Language Ability. Collectively these reveal a strong level of reliability for the overall assessment of narrative language across examinees. Test-retest reliability revealed a coefficient of 0.93 for the composite of Narrative Language Ability and 0.85 and 0.82 for the Comprehension and Production subtests, respectively. Lastly, interscorer reliability resulted in a coefficient of 0.99 for composites, Comprehension and Production.

Regarding test validity, the authors provide extensive measures to assess and meet expectations of test validity. First they provide detailed explanation and rationale to meet content-description validity, revealing the literature regarding narrative type and both the comprehension and production option. Additionally, they included various quantitative measures that link to content-description validity. For example, a quantitative item discrimination correlation revealed satisfactory to larger than satisfactory correlation between items and overall test score. The authors provide a criterion-prediction validity analysis comparing the TNL-2 subtest and composite raw scores with The Systematic Analysis of Language Transcripts software (SALT; Miller et al. 2011). SALT is used to calculate word-level analysis, sentence-level analysis, and story analysis of a narrative. Recordings of 142 of the children samples were selected for this transcription and language analysis using their Alien's story. Correlations between SALT scores and the TNL-2 ranged from moderate on the comprehension subtests to large on both production and composite scores, revealing scores on the TNL-2 as related to the types of language measures commonly applied to narrative language samples. Additional information regarding performance by differing diagnostic groups reveals the capability of the TNL-2 to correlate to those groups known to have compromised language as a result of their diagnosis.

Clinical Uses

The outcomes from the TNL-2 can provide initial understanding of the individual's language skills

underlying their narrative comprehension and production. The outcomes can be used to indicate general estimate of language ability and be a guide for further assessment and evaluation. The assessment may be beneficial to assessing growth overtime as well. Use of the assessment to select long-term goals is recommended and not recommended for short-term objectives. It may be possible for the examiner to conduct an error analysis of the individuals produced narratives to identify macrostructure and microstructure strengths and challenges to inform short-term objectives.

Test of Nonverbal Intelligence (TONI-4)

Joy Fopiano

Department of Elementary Education, Southern Connecticut State University, New Haven, CT, USA

Synonyms

TONI

Description

The Test of Nonverbal Intelligence, Fourth Edition (TONI-4), is an individually administered cognitive assessment instrument constructed in 2010 to assess general intellectual functioning. The test may serve to support an understanding of intellectual impairment, treatment therapy, or any special service needs. This tool is able to eliminate complex language and motor requirements that typically influence the results of more traditional measures of intellectual ability. This test is not designed for those who may be visually impaired. This assessment tool, published by Pro-Ed in Austin, Texas, can be administered individually in 15–20 min to children aged 6:0 and adults aged 89:11. Results exhibit skill areas measuring intelligence, aptitude, abstract reasoning, and problem solving. The publishers offer this “language-free” test as an alternative assessment measure for those who may be challenged with language, hearing, and/or motor abilities. This may also help to serve populations of individuals who may be unfamiliar with American culture. Directions may be delivered in English, Spanish, French, German, Chinese, Vietnamese, Korean, and Tagalog. In the complete test kit, there is a manual, picture book, critical reviews, and research findings (1982–2009), Form A and Form B record forms.

The first 19 questions are designed for ages 6–9 years, and the remaining questions are

designed for ages 10 and older. Each correct response is scored as 1 point and incorrect responses are scored with a 0. Each item contains one or more of the eight salient characteristics:

1. Shape
2. Position
3. Direction
4. Rotation
5. Contiguity
6. Shading
7. Size
8. Movement

A basal is achieved when the highest level at which an individual scores five consecutive correct responses is recorded. A ceiling is achieved when the third error out of five consecutive responses is recorded. Both TONI-4 forms can be used for research purposes and for periodic reevaluation. Scores are available as index scores where the mean is 100 and the standard deviation is 15. Percentiles, age equivalents, and descriptive terms (IQ greater than 130 = very superior, 121–130 = superior, 111–120 = above average, 90–110 = average, 80–89 = below average, 79 and below = poor) are presented. The manual provides a corresponding descriptive rating with each index score interval.

The oral instructions are simply stated. Individuals being administered the TONI-4 may respond with gestures including pointing, nodding, and blinking, thereby making this test available to both language-challenged and motorically challenged individuals. The 60 TONI-4 test items are arranged, as with other cognitive assessment tools, in an easy-to-difficult order. The authors have chosen items intended not to be influenced or challenged by educational, cultural, or experiential backgrounds. This assessment measure then can provide cognitive information for a diverse population of both children and adults for whom language and/or motor challenges may exist. The TONI-4 can be accessible for a wide range of varying needs and allow examiners and test takers to achieve results in a relatively short period of time.

Historical Background

The TONI-4 exhibits some decrease in cultural language factors which often influence verbally based tests. This 2010 updated current version of the TONI-3 has newly added several major non-English languages for non-English examinees who do not require nonverbal instructions. This is an important change allowing this cognitive measure to be administered with verbal instructions to a variety of diverse and/or multicultural individuals. These expanded languages could offer support for this tool to be a potentially welcome addition in a highly diverse school district.

In this most recent version of the Test of Nonverbal Intelligence (TONI-4), there is new normative data which has been collected and stratified. There is also the addition of six items from the TONI-3 to increase the level of challenge of the assessment measure. These items were added to address the previous concern which found that the test was not well suited for those who may be found to be in the gifted and talented population. The new items are stated to have improved the floor of both forms. Items have been reordered to balance the forms in the TONI-4.

The TONI-4 Kit includes:

Examiner's manual

Picture book

Critical reviews and research findings
(1982–2009)

50 Form A answer booklets and record forms

50 Form B answer booklets and record forms

Sturdy storage box

Some potential weaknesses of the TONI-4 emerge when considering that this assessment tool is designed for those who may be culturally or linguistically challenged. These notations include a small (23%) normative sample of individuals who were administered the test using the nonverbal instructions. Again, given that this tool is designed for those who may not be fluent with language, it is important to consider that the information gathered from the sample size is largely based on responses delivered through a verbal mode. Seventy-seven percent of participants in

the sample size utilized the verbal format. Further, none of the sample participants were given the non-English verbal formats of the test within the sampled population. Perhaps additional numbers within a sample size for the future, both within the population of nonverbal and within the population on non-English speakers, may be considered given that these persons are those for whom the test is especially designed to assess accurately. However, it is critical to note that stratification for the TONI-4 illustrates percentages which are consistent with the representative population of the United States.

Psychometric Data

Test Construction

The TONI-4 is an individually administered cognitive assessment tool which examines problem solving skills in a range of persons from 6 years 0 months through 89 years, 11 months. Each item contains features: shape, position, direction, rotation, shading, size, and movement. The more differences, the more complicated types and the greater number of rules the item has. Each form, A and B, has 60 items by adding the beginning and the end of the test to reduce the floor and ceiling effects, and the two were equally allocated in item similarity and difficulty by sorting all the items in difficulty.

Clinical Uses

The TONI-4 may serve as a strong and viable alternative as an individually administered cognitive measure for those individuals who may be challenged by language, hearing, motor, or American culture. Where instruments such as a WISC-IV, WAIS-IV, SB5, or WJ Cognitive Assessment do not suit, the TONI-4 may allow a closer look at individual abilities, especially problem solving and abstract reasoning, and support any diagnosis regarding intellectual functioning. The TONI-4 can be a strong alternative to other more verbally laden tools of individual assessment. It could also be utilized to support a special services need. To

utilize and interpret the TONI-4, test administrators need formal training and a fundamental understanding of mental ability testing and measurement.

Test Construction

The TONI-4 is an individually administered measure used to assess problem solving without a requirement of the testee of a language or motor skill. Each item contains features of shape, position, direction, rotation, shading, size, and movement. The greater the difficulty, the more complicated types and the greater the number of rules each item contains. Examiners can use this tool to help shape hypotheses for learning and planning that do not bias children or adults with language or culturally laden items. Indeed, the directions may be administered in a variety of languages.

There are two test forms: form A and form B. Each contains 60 items. Adding items at the beginning and at the end of the two forms was done to reduce the floor and the ceiling. Effects of the two were equally allocated in item similarity and difficulty by sorting all the items by difficulty. If three errors occur within five items, the last incorrect item is the ceiling. Conversely, with five correct responses, the last item is the floor item. If a test-taker cannot understand the expectation after two times of a training item, the testing should be ceased. Otherwise, an examiner would discontinue testing once a ceiling has been reached.

Item Analysis

A point-biserial correlation between each item and the total scores resulted in enough magnitude for positive content validity. Item difficulty averaged about 50% with items ranging between 15% and 85% which is an acceptable degree for item discrimination. The distribution was evenly spread.

Item Response Theory

A logistic regression was used on all test items. Three dichotomous groups were compared by effect sizes (e.g., male vs. female, African American vs. non-African American, and Hispanic

vs. non-Hispanic). The results show the items are unlikely to be biased. Items that did show moderate (34–70%) or large bias (greater than 70%) were deleted and replaced with other nonbiased items.

Standardization Sample

The robust standardization sample included 2,272 participants from 31 of the United States. Those states were further broken down and examined by regions within the United States including: South, West, Northeast, and Midwest. All assessments were performed by experienced trained specialists. The verbal instructions were delivered in English, and this form was used for 77% of the normative sample. The remaining used the nonverbal instructions provided. The sample was proportionally stratified relative to the United States population at the time the test was developed. Age, race, gender, location, parental education, and socioeconomic status were all considered, each of which was hypostasized to potentially influence cognitive ability.

Reliability and Validity

Test-retest ability showed ($N = 63$) consistency for both forms. This was true for immediate and delayed administrations. Interrater reliability showed strength among experts who administered the tool. These findings may be interesting for those who may wish to use this tool to update their understanding of an individual who is language challenged and where planning for needs may be better understood.

Strengths

The first strength of the TONI-4 is that it can be administered with clear and easy-to-understand instructions in 15–20 min to a diverse array of children and adults aged 6–89 years. That a cognitive assessment instrument can be administered in a short period of time to such a wide range of individuals is an asset by itself. Beyond this, however, it is possible to provide oral directions in a variety of languages serving the linguistically diverse national population as well as nonverbal directions to those who may benefit to grasp without a language requirement. Test-taking responses

do not have motor or language-based requirements, making this again accessible to a wide range of individuals with varying needs.

The manual for the TONI-4 provides instructions that are both verbal and nonverbal. There is evidence of a decrease in the cultural factors. There is new normative data that has been collected and stratified and six items were added to increase the measure's level of challenge. This is in response to earlier critique that the tool did not assess for those qualified as gifted and talented. These items improved the floor of both forms. Items were also reordered to balance the forms. In short, this tool may reach a population subset of individuals that have been a challenge to assess with accurate well-normed tools previously.

Weaknesses

The normative sample was tested with the English version. 23% of the sample was administered the test using the non-verbal instructions. Therefore, some of the stratification subgroups may be perceived to be small (e.g., exceptionality subgroup 13% and adults with disability 7%); however, it is noted that this was representative of the United States population at the time the norming was completed. Still, with smaller groups, there may be some question about the reliability and validity. Additional numbers may be useful for the future given that the test authors are offering this tool to support certain populations.

Summary

The TONI-4 is considered to be user friendly. It can be a time-efficient cognitive measure that can be individually administered to a multicultural and physically diverse population of children and adults aged 6–89 years. This cognitive measure does not require language or advanced motor skill of the participant. Visual skills are required. The TONI-4 could be seen as a potential tool for schools to utilize who have diverse student populations. Those taking the test have the option of responding with simple gestures such as pointing, nodding, or blinking which opens up opportunities to use this tool with diverse

populations of learners. Professionals, then, can consider this assessment as part of a battery to examine general intellectual functioning, diagnose intellectual impairments, and verify referrals for special services and for research purposes.

Test of Playfulness (ToP)

Anne Snow
Child Study Center, Autism Program, Yale
University, New Haven, CT, USA

Synonyms

ToP

Description

The Test of Playfulness (ToP) is an assessment designed for measuring the play of individuals between the ages of 6 months and 18 years (Bundy 2010). It is composed of 29 items that are scored following an observation of the individual's free play in both indoor and outdoor

settings. It has been recommended that the ToP is most reliable when completed after play sessions that are 15 minutes in length. The ToP is completed by a trained observer. Items are scored on a 4-point Likert scale with respect to three dimensions: Extent (0 = rarely or never, 3 = almost always), Intensity (0 = not, 3 = highly), and Skillfulness (0 = unskilled, 3 = highly skilled).

Scoring the ToP utilizes a test-specific Keyform, which depicts the relative difficulty of each item plotted against the means and standard deviations for the items. Recording the item scores on this form produces a total score ranging from −7 to 7.

Historical Background

The initial version of the ToP was a 60-item assessment completed by a rater who scored from videotaped segments of free play. It has undergone three revisions, leading to the current version (Version 4). The first and most significant revision took place in 1993. Items were eliminated from the previous version. Those that were eliminated were items in which the statistical analyses indicated did not contribute toward the construct of playfulness or were difficult to observe reliably. New items were also added in order to increase the ability of the measure to detect subtle changes as a result of intervention. In addition, the scoring procedure was revised to include the Intensity and Skillfulness scoring scales. The second revision took place in 1997, which consisted of subtle revisions to the item set, with a subsequent minor revision clarifying scoring criteria. The most recent revision to ToP was completed in 2000. This revision came about in response to the growing number of examiners who were using the ToP to assess children with autism spectrum disorders (ASD). The goal of this revision was to make the ToP more sensitive to changes in playfulness as a result of intervention, as well as to add a greater number of easier items to adequately capture the play skills of children at lower levels of functioning. Seven new items were added to address this goal.

Psychometric Data

Throughout the development of the ToP, data have been collected from nearly 2000 children. Rasch analysis was used to validate the measure. This type of analysis measures the extent to which the difficulty of items corresponds to the ability of the individual. In other words, this analysis indicates whether more capable individuals (in this case, more playful) have higher scores on the ToP. Data from 96% of the items, 93% of the participants, and 95% of the raters have met this assumption, thus indicating that the ToP items reflect a unidimensional construct of playfulness.

The test-retest reliability of the ToP has been examined in one published study (O'Brien and Shirley 2001). Overall, it appears that the stability of the test scores is high. However, some variability in scores is expected as a function of the environment in which the play observations are conducted. In situations with several potential play activities or partners, the reliability of the test scores have been found to be lower (Skard and Bundy 2008). Researchers have suggested that if a child is to be evaluated on the ToP twice (e.g., to assess change in playfulness following an intervention), the child should be alone or with a playmate in both assessments in order to increase consistency between the play settings.

Clinical Uses

The ToP was developed as a tool to be used by occupational therapists as a formal assessment of the playfulness of their clients. The authors of the ToP indicate that it should be used by clinicians who desire to assess and promote play and playfulness in their young clients. Although it was originally intended to be used by occupational therapists, members of other professions are encouraged to use the ToP in assessments that would benefit from an evaluation of playfulness. As play skills are often impaired in children with ASD, the ToP may be a useful addition to the assessment of this population (Baranek et al. 2005).

Test of Pragmatic Language-2 (TOPL-2)

Joanne Valdespino

Test Development, PRO-ED, Inc., Austin, TX, USA

Synonyms

[TOPL-2](#)

Description

The *Test of Pragmatic Language, Second Edition* (TOPL-2; Phelps-Terasaki and Phelps-Gunn 2007), is a standardized, norm-referenced test designed to effectively assess pragmatic language ability in students and provide in-depth, comprehensive analysis of social communication in context. Its principal uses are to identify individuals with social language deficits, determine individual strengths and weaknesses, develop a remedial

program, assess metapragmatics, and provide a tool for continued research in pragmatic language skills.

In the pragmatic language model of the TOPL-2, social communication is represented as an interconnected function of a student's ability to appropriately analyze, respond, and integrate situational, discourse, and semantic contexts of language (Phelps-Terasaki and Phelps-Gunn 2007). The TOPL-2 uses narrative and story contexts that reflect the dynamics of daily social interaction typically experienced by school-age children. Verbal and picture prompts are used to create a story or problem situation, and the student is asked to generate responses that make sense, fit the situation and context, and are likely to be successful, which is to say that they "work" effectively.

The TOPL-2 is developed for use with individuals between the ages 6 and 18 years. It can be individually administered in 45–60 min. The TOPL-2's 43 items measure various aspects of pragmatics (i.e., physical context, audience, topic, purpose, visual-gestural cues, and abstractions). Nineteen of the 43 items contain a pragmatic evaluation (PE) subcomponent, which measures the student's ability to monitor and appraise their own social language usage. The test's 43 items combine to produce a standard score, called the Pragmatic Language Usage Index. Administration of the PE items is optional but gives the examiner further information which may be used in individual educational plans and remedial plans.

Historical Background

The *Test of Pragmatic Language* (TOPL) was published in 1997 in response to the need for a standardized assessment instrument to measure the use of language in a social context. The TOPL-2, published in 2007, made improvements and refinements of the test based on new research in social language, new ideas for more in-depth layers of evaluation, and user feedback on the first edition of the test.

The TOPL-2 model is based on Norris and Hoffman's (1993) model of pragmatic language

known as the Situational-Discourse-Semantic (S-D-S) model. The S-D-S model serves as a framework for conceptualizing language in school-aged children. Language functioning in the S-D-S model falls under three contexts: situational context, discourse context, and semantic context.

The TOPL-2 authors adapted Norris and Hoffman's model and further developed subcomponents for each S-D-S context. The situational context represents the physical environment and the audience to which the conversation is directed. The discourse context concerns the function and effectiveness of language and is represented by the topic and purpose subcomponents of the TOPL-2 model. Semantic context refers to the aspects of language that are used to convey ideas or concepts. Semantic concepts in the TOPL-2 model have three subcomponents: visual-gestural cues, abstract language, and pragmatic evaluation.

Psychometric Data

The TOPL-2 was normed on a representative sample of 1136 students reflective of US school-age children. Data were matched to US Census reports on race, gender, rural or urban residence, ethnicity, family income, parent education, and disability. Raw scores on the TOPL-2 can be converted to standard scores (mean of 100 and a SD of 15), percentile ranks, and age equivalents.

The reliability of the TOPL-2 was estimated using Cronbach's coefficient alpha (content sampling), test-retest (time sampling), and correlation between scorers (scorer differences). The average coefficient alpha for the Pragmatic Language Usage Index at 13 age intervals yields an average reliability coefficient of .91. The TOPL-2 test-retest coefficients exceed .90, showing good time stability. TOPL-2's interscorer reliability was .98.

The TOPL-2's validity was estimated using content-description, criterion-related, and constructed-identification methods. Items of the TOPL-2 were written to reflect Norris and Hoffman's (1993) S-D-S model and rated by 12 experts regarding the relevance of each item to subcomponents of the TOPL-2. Item analysis

studies indicated a median item difficulty of approximately .50 and median item discrimination coefficients which exceed .35 at every age. Items on the TOPL-2 were tested for bias using logistic regression procedures. Only one item indicated bias toward gender or ethnic subgroups.

Criterion-prediction studies compared examinee performance on the TOPL-2 with performance on the *Comprehensive Assessment of Spoken Language* (CASL; Carrow-Woolfolk 1999), *Pragmatic Language Skills Inventory* (PLSI; Gilliam and Miller 2005), and *Test of Adolescent and Adult Language, Fourth Edition* (TOAL-4; Hammill et al. 2007). The relationship between the TOPL-2 and criterion tests ranged from .80 to .97.

Other validity studies described the TOPL-2's relationship to age and IQ. The performance of various subgroups was analyzed as well. The correlation between chronological age and performance on TOPL-2 was .64. The performance of selected subgroups of gender, ethnic background, and exceptionality subgroups was within expectations. The correlation between the TOPL-2 index and the *Wechsler Intelligence Scale for Children, Third Edition* (WISC-III; Wechsler 1991) was .52.

Clinical Uses

TOPL was originally designed for use by speech-language pathologists. However, with the ever-increasing emphasis on social skills and conflict resolution in students, TOPL-2 test provides essential information for all team members: school psychologists, counselors, clinical psychologists, and special education teachers and specialists. These varied team members can use the TOPL-2 as part of a full individual evaluation and program planning.

The TOPL-2 can be used for a variety of purposes such as to identify students who have difficulty using social language, to determine a student's progress in pragmatic language development, to measure social language deficits in certain populations or to explore the relationship between social language ability and emotional

behavioral problems and academic performance, and to aid in evaluating specialized interventions.

Test of Sensory Functioning in Infants

Tara J. Glennon
Occupational Therapy, Quinnipiac University,
Hamden, CT, USA
Centre of Pediatric Therapy, Fairfield and
Wallingford, Wallingford, CT, USA

Synonyms

TSFI

Description

This assessment tool offers an objective method to examine the sensory functioning of infants aged 4–18 months. In an effort to provide an objective method to determine whether, and to what extent, an infant has sensory processing deficits, this tool provides a score for each of the 24 items. These test item scores are then calculated to establish an overall score of sensory processing and reactivity (total test score), as well as a score within each of the following sensory subdomains of sensory functioning:

1. Reactivity to tactile deep pressure
2. Visual tactile integration
3. Adaptive motor function
4. Ocular motor control
5. Reactivity to vestibular stimulation

The above subdomains were identified for inclusion in this tool for specific applicability to infant behavior. For example, measuring how an infant responds when touched in sensitive areas (i.e., soles of feet, stomach, or mouth) is important as tolerance to touch experiences is critical for mother-infant interaction. Additionally, a child who does not tolerate touch (reactivity to tactile deep pressure) or movement experiences (reactivity to vestibular stimulation) “may avoid tactile contact, being held and moved in space, and may avert his or her gaze to avoid face-to-face interaction” (DeGangi and Greenspan 1989, p. 4). Observing how a child visually locates and tolerates the touch of various objects is important as these are some of the first steps to object exploration and then creating plans of action on how to manipulate an object.

It is suggested that a practitioner (i.e., pediatrician, psychologist, infant educator, occupational therapist, physical therapist), with a baseline understanding of sensory processing, allows 2 h to learn the items prior to implementation. The assessment manual is easy to follow, and the specific instructions for item implementation are outlined with pictures to assist. A score of 0, 1, 2, or 3 is received depending on the child’s response to each item. The higher the

score indicates a more integrated, organized, or normal response. Lower scores qualify other responses as no response, partial response, disorganized response, hypo-reactive response, or adverse or mildly defensive reaction. The score tallies in each subdomain then result in a “normal,” “at risk,” or “deficient” score profile. It should be noted that at the time of development, 1989, practitioners only had their clinical judgment to determine if sensory issues were present in an infant. Thus, this criterion-referenced assessment tool was a marked improvement for the time and thus assisted in clinical practice as well as research.

Historical Background

Well-known and respected early childhood specialists, Georgia DeGangi, Ph.D., OTR (occupational therapist who now practices in clinical psychology) and Stanley Greenspan, MD (who later developed the Floortime Approach™), developed this objective tool to observe and measure the sensory processing abilities of infants. At the time, the only formalized measurements of children of this age were to measure motor and neurological functions but not the possible underlying sensory dysfunction which resulted in these identified motor or perceptual difficulties. The thought, based on sensory integration theory (Ayres 1964, 1972, 1979), was that intervention directed at potential underlying sensory processing difficulties would be most effective in addressing any resulting motor or perceptual deficits. A fuller description of Ayres’ theory of sensory integration can be found in the links below titled ► [“Ayres, A. Jean”](#), ► [“Sensory Processing”](#), and ► [“Sensory Integration \(SI\) Therapy”](#).

Psychometric Data

The test manual specifically outlines each step of the sampling and statistical procedures. However, it should be noted that there were some sampling difficulties specifically associated

with distinguishing typical irregularities (i.e., colic which might be noted up until 6 months of age) from clinical issues measured by the assessment.

Table 1 outlines the components of the assessment process including the psychometric procedures associated with the development of this criterion-referenced assessment tool. In summary, the total test score can be used reliably and validly for screening decisions, and the subtests can be used reliably and validly under certain age or diagnostic conditions based on the following information:

- Content validity: The test has a moderate to high degree of content validity.
- Construct validity:
 - Due to false error rates, the test should not be used on infants with delays or regulatory disorder until the infant reaches 10 months of age (DeGangi and Greenspan 1989, p. 29).
 - The subdomains of behavior investigated by the TSFI were distinctly different from other scales and assessments available at the time of development.
- Interobserver reliability: There were high levels of consistency in the identification of the classification designated for each item.
- Test-retest reliability:
 - Stability was good for visual tactile integration, ocular motor control, and the total test score.
 - Stability was fair for reactivity to tactile deep pressure.
 - Stability for reactivity to vestibular stimulation and adaptive motor functions were not strong enough to base decisions on, and a retest of these items should occur to substantiate initial findings of normalcy or dysfunction.

Clinical Uses

Any assessment tool should be used in combination with other tools in order to gain the most

Test of Sensory Functioning in Infants, Table 1 TSFI assessment review

Test name: Test of Sensory Functions in Infants (TSFI)
Author(s): Georgia A. DeGangi, PhD, OTR and Stanley I. Greenspan, MD
Publisher: Western Psychological Services, 625 Alaska Ave, Torrance, CA 90503; 800-648-8857
Technical information: 2 h of practice before administering
Age range(s): 4–18 months
Assessment type: Criterion referenced
Reliability: 1. <i>Interobserver reliability</i> : Obtained through 2 observers (PT & OT) for the same set of responses; 41 infants participated within 7–12-month age ranges. Intraclass correlations for the subtests and total test were high with coefficients ranging from .88 to .99 2. <i>Decision-consistency reliability</i> : The p_o index of decision consistency was used to determine “the proportion of children classified as normal and delayed on repeated testings” indicating a degree of confidence for the decision (i.e., the stability of the decisions). A sample of 26 “normal” infants was tested twice using a 1–5-day interval of retests. The age range consisted of 4–18 months consisting of 10 boys and 16 girls. Utilizing five observers, observer errors of measurement were affected because the same observer was not always able to conduct the retest on the same infant. The p_o index displayed that the five subdomains and total test ranged from 81% to 96%, indicating high levels of overall classification consistency 3. <i>Test-retest reliability</i> : The Pearson product-moment was used to calculate the stability of individual scores between the test and retest (five observers). In addition, some evidence indicates that some sensory integrative functions may be unstable (Ayres 1980), and this may affect the stability of coefficients Results: Good: Visual tactile integration, ocular motor, and total test scores Fair: Reactivity to tactile deep pressure Poor: Reactivity to vestibular stimulation and adaptive motor functions Twenty of the 26 infants were between the ages of 4 and 6 months old, thus leading to more variability in responses. This concludes that more extensive research should take place
Validity: 1. <i>Content validity</i> : A two-stage judgmental review occurred to determine test validity. Congruence and representativeness were rated by eight judges. They rated the subtests of the assessment with regard to their ability to overall measure the infant population’s sensory functioning. Congruence was rated either as poor, moderate, or high for each item <i>Item-behavior congruence</i> : High ratings (75–85%) for item-behavior congruence for all items. Two of the eight judges rated moderate for the items of the vestibular

(continued)

Test of Sensory Functioning in Infants, Table 1
(continued)

stimulation and reactivity to deep pressure. One judge gave a low rating for the adaptive motor function test and the visual tactile integration test

Representativeness: High ratings (87%) for all subtests except for a rating of 75% which was used for the reactivity to vestibular stimulation. The concept of “stranger anxiety” was discussed as a possible influence on the vestibular score. Several items (several domains) were ultimately discarded as not sufficiently discriminating or differentiating the sample

2. *Construct validity:* Construct validity evidence was found within the item, subtest, and test and was based on criterion-group performance comparisons. The validity was found by computing a discrimination index displaying the difference between group item performance and the mean score for regulatory, normal, and delayed disorder groups. Subtest intercorrelations were computed to display evidence that each subtest measures a different subdomain of behavior and, thus, are worthy of administration

Item validity: Out of the 44 test items, 20 were taken out after item analysis since they did not discriminate between the groups of delayed and normal or regulatory disorder infants, or were not sensitive to the normal infants’ developmental status

Decision validity: The focus of these cut-off decision procedures was to minimize the false-normal error rate (thought to be the more serious type of error in the diagnostic or screening process). Results were as follows:

False-normal error rate across age ranges:

Reactivity to tactile deep pressure and reactivity to vestibular stimulation subtests: between 0% and 59%

Adaptive motor functions, visual tactile integration, and ocular motor control: between 29% and 100%

False-normal error rate for 4–6-month-old age range: 75% for the total test with adaptive motor functions and visual tactile integration subtests least effective as these functions are just beginning to emerge

False-normal error rate for 7–18-month-old age range: between 14% and 45% for the total test

False-delayed error rate was minimized by setting the cut-off scores: ranged from 1% to 29% for the various subtests and age ranges, and from 7% to 19% for the total test

Test structure: Low coefficients between subtests indicate that this subtest is measuring a distinctly different function. Results, as follows, furnish evidence of the benefit of administering all five subtests:

Very low coefficients were found for the correlations of reactivity to vestibular stimulation and other subtests

Very low coefficients were found for the correlations of reactivity to tactile deep pressure and the other subtests

High correlations of .40–.47 were found between the adaptive motor functions, visual tactile integration, and ocular motor control subtests. This is not all that surprising as each of these measures a motor response or a motor output to a sensory response

(continued)

Test of Sensory Functioning in Infants, Table 1
(continued)

All coefficients were relatively low, ranging from .02 to .47, indicating that each subtest is measuring distinctly different sensory functions from the others

Obtaining information: 24 items should be administered individually, and in one setting, items should be administered exactly as described in the manual

Family’s role in the assessment process: The caregiver must be present during administration to hold the child and/or assist if needed

Time to administer: 20 min

Time to score: 5 min

Materials included in the test kit? X yes no

Describe materials: hand puppets, tennis ball, yarn, paper, furry mitt, etc.

Testing procedures

Is the tool easy to learn and administer? X yes no

How much training or practice is required? 2 h

Who can administer the test? Designed for pediatricians, psychologists, infant educators, occupational therapists, and physical therapists. A background in sensory processing is recommended

Is the manual easy to follow/understand? X yes no

Are the forms easy to follow/understand? X yes no

Domains: Reactivity to tactile deep pressure, adaptive motor functions, visual tactile integration, ocular motor control, and reactivity to vestibular stimulation

Outcome: Each subdomain/subtest will identify or determine an adverse, mildly defensive, or integrative response or reaction. It can also be used in conjunction with other developmental tests to provide an overall indicator of the child’s developmental functioning

comprehensive picture of a child’s functioning. The TSFI was intended to provide information related to the five subdomains noted above as these categories of sensory functioning were thought to be the most impacting on the development of efficient sensory integration in infants. The intent was to administer this assessment to “infants with regulatory disorder, developmental delay, and those at risk for later learning and sensory processing disorders (e.g., high-risk premature infants)” (DeGangi and Greenspan 1989, p. 2).

This tool continues to be utilized today in clinical practice as it is a very structured and organized method to investigate the sensory

processing abilities in this age group. Other standardized tools attempting to reliably measure sensory processing in this age group include the *Sensory Profile – Infant/Toddler* (Dunn 2002), *Sensory Processing Assessment* (Baraneck 2010), and *Sensory Processing Measure – Infant/Toddler* which is currently in development by the authors of the *Sensory Processing Measure* (Parham et al. 2007) and *Sensory Processing Measure - Preschool* (Kuhaneck et al. 2010).

Test of Written Language

Tiffany Hutchins

Department of Communication Sciences and Disorders, The University of Vermont, Burlington, VT, USA

Synonyms

Test of Written Language, Fourth Edition (TOWL-4)

Description

The Test of Written Language, Fourth Edition (TOWL-4; Hammill and Larsen 2009), is designed to be a comprehensive assessment of the writing abilities of students between the ages of 9 and 17 years and 11 months. The testing materials include a student response booklet (Forms A and B), a record/story scoring form and a supplemental practice scoring sheet, illustrations to elicit writing samples, and an examiner's manual.

The TOWL-4 is comprised of seven subtests intended to sample a wide range of writing competencies. Five subtests (Vocabulary, Spelling, Punctuation, Logical Sentences, and Sentence Combining) use a contrived format intended to assess isolated units of written language (e.g., use of punctuation, spelling from dictation). An additional two subtests (Contextual Conventions, Story Composition) follow a spontaneous format designed to assess a students' functional writing ability. "Such assessment focuses on evaluating the quality of actual passages composed by students. To write effectively in everyday life or school situations, students must be proficient in using all of the writing components" (Hammill and Larsen 2009, p. 4).

The test begins with the collection of the spontaneous writing sample. The student is shown a sample illustration (one that shows preparations for a birthday party where chaos has erupted). The administrator reads an "example of a good story" to accompany the picture and explains what

makes this a good story (e.g., it has a clear beginning, middle, and end; people in the story have names and emotions). The student is asked to write a story about another picture and to “try to make your story as interesting as you can.” Students are given 20 min (5 to plan and 15 to write) to finish the story.

The test continues with the administration of contrived contexts. Examples of each task are given to ensure that the student understands what is being asked. No time limits are imposed for these tasks but students are encouraged to progress rapidly and not spend too much time on any particular item. Items in each subtest increase in difficulty. Testing always begins with the first item and progresses until the ceiling (three incorrect responses in a row) is reached.

The first subtest, Vocabulary, includes 33 items. For each item, a written word is presented (it is never spoken), and the student is asked to incorporate the word into a sentence without changing it in any way (e.g., “ran” can be incorporated into “I ran to the store”). Subtests 2 and 3 (Spelling and Punctuation, respectively) are administered using 26 sentence dictation items (e.g., “You can go with me” or “Because of the confusion, she sought legal help”). Subtest 4, Logical Sentences, uses 22 sentences that contain some form of flawed logic. The child is asked to correct each sentence (e.g., “The dog moored loudly” should be changed to “The dog barked loudly”) by marking those changes on the form (e.g., crossing out, writing in). Subtest 5, Sentence Combining, includes 23 items. Each item consists of 2–4 sentences that can be combined into a single sentence (e.g., “Tom is big” and “Tom is a man” can be combined to form “Tom is a big man”). For each of the subtests comprising the contrived portion of the TOWL-4, correct answers are provided in the examiner’s manual. Well-reasoned guidance is also provided to help administrators make decisions for sentences that are difficult to score.

Two additional subtests are intended to evaluate the quality of the student’s spontaneous language sample gathered at the beginning of the test. Subtest 6, Contextual Conventions, contains 21 items which rate a number of contextual

dimensions. Each item is accompanied by either a nominal or ordinal scale. For example, the first item (“Sentences begin with a capital letter”) uses an ordinal 0 (three mistakes or more), 1 (one to two mistakes), or 2 (no mistakes). By contrast, item 6 (“Uses a question mark”) employs a nominal 0 (no) or 1 (yes) system. Subtest 7, Story Composition, is similar in design, but it contains 11 items intended to tap aspects of story composition (e.g., sequence, plot). These examples are ones in which there is a rather clear criterion to justify a rating. This is not true, however, for all items in the spontaneous format. For example, item 6 of the Story Composition subscale requires a rating for “Story Action or Energy Level (Pace).” Here, the administrator is asked to make a judgment of either 0 (plodding, stumbling, none), 1 (interesting, sustained), or 2 (exciting, compelling, exceptional). Unlike the scoring of the subscales for the contrived formats, little guidance is offered, and to the degree that these ratings are subjective, errors will be introduced during scoring. A summary of the subscales comprising the TOWL-4 is presented in the Table 1.

Scores can be generated for each subtest as well as composite scores for the contrived and spontaneous tasks, and an overall writing score. Scores are available in the form of raw scores, percentile ranks, grade and age equivalents, and scaled scores which are particularly useful for making comparisons to the normative sample.

Historical Background

The original TOWL (Hammill and Larsen 1978) was developed to respond to the need for a comprehensive test of written language. At that time, only the Picture Story Language Test (Myklebust 1965) was available and concern was growing over the outdated, unrepresentative normative data and the validity of the tool more generally (Hammill and Larsen 2009). Since its original publication, developers of the TOWL recognized the need to assess written language using both contrived and spontaneous formats. Contrived formats are desirable because they are more traditional and, thus, more familiar to test

Test of Written Language, Table 1 Description of subtests on the Test of Written Language

<i>Contrived formats</i>	Description
Subtest 1: vocabulary	The student is asked to incorporate a single written word into a written sentence (33 items)
Subtest 2: spelling	The student writes from dictation, and spelling is inspected for correctness (26 items)
Subtest 3: punctuation	The student writes from dictation, and punctuation is inspected for correctness (26 items)
Subtest 4: logical sentences	The student is asked to identify and correct logical errors within sentences (22 items)
Subtest 5: sentence combining	The student is asked to combine relatively short and simple sentences into a single, more complex, sentence (23 items)
<i>Spontaneous formats</i>	
Subtest 6: contextual conventions	The examiner rates the quality of the student's spontaneous narrative with regard to several writing conventions (e.g., correct capitalization) (21 items)
Subtest 7: story composition	The examiner rates the quality of the student's spontaneous narrative with regard to several dimensions of story composition (e.g., sequence) (11 items)

administrators. They are also well suited for isolating and assessing discrete units of written discourse (e.g., spelling, punctuation). On the other hand, spontaneous formats (i.e., written story elicitation in response to a visual stimulus) were also seen as essential to content validity. In analysis of the spontaneous format, the story can be scrutinized for the quality of its composition, creativity, and intellectual merits (Hammill and Larsen) which is not possible using the contrived format. This basic distinction between contrived and spontaneous formats for analyzing written language underlies the design of the original TOWL (Hammill and Larsen 1978) and all of its revisions (i.e., Hammill and Larsen 1988, 1996, 2009). What has changed with each revision is the number and content of the subscales that make up the contrived and spontaneous formats and the specific administration and scoring procedures that accompany them.

Although the original TOWL (Hammill and Larsen 1978) was generally described by reviewers as an ambitious and commendable undertaking and one that represented a real contribution, criticism was reported. Major questions surrounded the characteristics of the normative sample and whether the test met industry standards with regard to reliability and validity (Hammill and Larsen 2009). The TOWL-2 was undertaken as the first major revision of the test, and “reviews for the TOWL-2 were even more encouraging that those for the TOWL” (Hammill and Larsen 2009, p. viii). Nonetheless, some questions about the description of the normative sample persisted. New concerns were also raised about the time length required to administer the TOWL-2 and subjectivity when scoring the spontaneous subtests (Davis 1990; Jacobson 1991). As Hammill and Larsen (2009) attest, “in our efforts to improve the statistical and theoretical properties of the test, we inadvertently made it cumbersome to give and tedious to score” (p. ix). The next major revision, the TOWL-3 (Hammill and Larsen 1996) was developed to overcome these difficulties and strengthen reliability and validity. Reviewers of the TOWL-3 were generally supportive of the psychometric properties of the test and agreed that the TOWL-3 was useful as a research and clinical tool. On the other hand, questions were raised about the presence of ceiling and floor effects (e.g., Bucy and Swerdlik 1998) which seriously limited the usefulness of the test when given to older or younger children. Moreover, concerns about the subjectivity of scoring (particularly with regard to the spontaneous format) remained. Thus, “although the TOWL-3 substantially improved over previous versions, a degree of subjectivity remains in the scoring procedures” with many of the subscales requiring judgments that are “inherently subjective and likely to provide a significant source of error” (Hansen 1998, p. 1071).

In the examiner's manual of the TOWL-4, Hammill and Larsen (2009) describe how the current version seeks to improve upon the test in several ways. Improvements include the use of normative data representative of US census statistics, the availability of both grade- and age-based

norms, and more conclusive evidence as to the measure's reliability and validity. Unfortunately, the problem of ceiling and floor effects continues for individual subscales but the authors note that neither of these occurs for the composite scores (Hammill and Larsen 2009). The psychometric properties of the TOWL-4 are briefly described below.

Psychometric Data

The TOWL-4 was normed on a sample of 2,205 individuals (ages 9–17 years) living in the United States. Demographic data were evaluated with regard to geographic area, gender, ethnicity, income, parental education, and exceptionality status, including individuals with autism spectrum disorder (ASD; 1% of sample). Normative data for all categories are comparable to recent US census statistics.

Several types of reliability of the TOWL-4 have been documented. Internal consistency, or the degree to which items on a test measure the same content domain, indicates a moderate to high degree of consistency for subscale and composite scores. An evaluation of alternate-form reliability was needed to establish the equivalency of the A and B test forms. Good reliability was achieved. The test-retest reliability over a 2-week interval is also acceptable indicating good temporal stability. The TOWL-4 should also have adequate interscorer reliability to demonstrate that scores are stable when different individuals administer the test. This is particularly important given previous concerns about the subjectivity and difficulty in scoring the test, especially the Contextual Conventions and Story Composition subtests of the spontaneous formats. Although the lowest estimates occurred with the Story Composition subtest, acceptable interscorer reliability was found between two trained raters who were familiar with TOWL-4 scoring procedures.

The validity of the TOWL-4 has also been assessed. First, the TOWL-4 appears to have adequate content validity, which is the degree to which the test covers the intended content domain. Indeed, the content of the TOWL-4 was developed

in line with the writing development literature, and the developers are convincing in their justification of each of the seven subscales included in the TOWL-4. To further support content validity, item analysis was conducted. Only items with conservative discriminating power and difficulty levels between 15% and 85% were included. Convergent validity, based on the ability of TOWL-4 scores to correlate with scores on a variety of performance measures, is moderate to very large. For example, subscale and composite TOWL-4 scores are significantly correlated with other literacy (e.g., the Test of Reading Comprehension – Fourth Edition; Brown et al. 2009) and intelligence (e.g., the Wechsler Intelligence Scale for Children – Fourth Edition; Wechsler 2003) measures. The authors of the TOWL-4 have demonstrated criterion-related validity by obtaining the expected correlations between TOWL-4 scores, age, and grade level.

In summary, the TOWL-4 is highly regarded as a comprehensive assessment of written language. Of course, users should be aware of the features that complicate administration and interpretation of the measure. Chief among these are the presence of ceiling and floor effects for many of the individual subscales, which makes their use for both older and younger children problematic. In addition, administrators require a degree of practice and familiarity with the measure before it can be administered and scored efficiently and reliably.

Clinical Uses

The TOWL-4 was designed to serve as a comprehensive assessment of written language. More specifically, its purposes are to identify students who may need special help with writing, to document students' writing strengths and weaknesses, to guide education planning, and to monitor the effectiveness of programs designed to support writing skills. Despite inclusion of a small number of individuals with ASD in the normative sample, the TOWL-4 was not developed for use with this population. It is intended for students with developing writing skills who may be struggling to achieve literacy milestones typical of their age- or grade-matched peers.

Of course, this could apply to special populations including those with ASD, especially those with higher cognitive and language skills for whom writing development has been identified as a goal in the student's education planning. Thus, the TOWL-4 may have some utility for professionals working with students with ASD in an educational setting and could be administered as part of a larger battery of tests designed to inform education programming across verbal and non-verbal means.

Clearly, each clinical application raises questions to consider when determining the appropriateness of the TOWL-4 and interpretation of scores for special populations. One advantage of the TOWL-4 is that it includes alternate forms that may be particularly useful in evaluating the effects of education programming. However, one serious concern involves the presence of floor and ceiling effects that are known to affect TOWL-4 subscale scores. This makes the literal interpretation of all derived scores perilous for older and younger individuals (with and without ASD). When ceiling or floor effects occur, professionals are advised to consider only the composite and overall writing scores. Of course, derived scores need not be obtained at all. Although the inspection of raw scores does not allow for comparison to the normative group (which is not equivalent to a population of students with ASD), informal inspection of the patterns of performance across subtests to identify relative strength and weakness areas in the context of dynamic assessment seems more justified.

Thalamus

Susan Y. Bookheimer
Department of Psychiatry and Biobehavioral Sciences, UCLA School of Medicine, Los Angeles, CA, USA

Definition

The thalamus is a brain structure located just above the midbrain near the center. It is a paired structure

(one in each hemisphere of the brain) shaped like small elongated spheres. Composed of many subregions each with unique functions and connections in the brain, the thalamus serves many different roles. One primary role is as a relay station between sensory input and the brain's primary sensory processing regions. All sensory input except olfaction stops first at the thalamus before reaching the neocortex. One major theory for thalamic function describes the thalamus as a sensory gating structure, in which sensory information is processed and filtered, perhaps for relevance, before proceeding to the brain (McCormick and Bal 1994). In addition to relaying sensory information to the cortex, the thalamus also receives top-down input from frontal cortex, which then proceeds to vast brain areas, including sensory association regions. The thalamus also plays an important role in regulating motor behavior. Finally, the thalamus is involved in regulating arousal and wakefulness through connections with the cortex, which may be involved in consciousness. Lesions to the thalamus can cause patients to enter into comatose states, as well as affecting motor, sensory, attention, and higher cognitive functions.

Thalidomide

Susan Hyman
Developmental and Behavioral Pediatrics,
Division Chief Neurodevelopmental and
Behavioral Pediatrics, University of Rochester
Golisano Children's Hospital,
Rochester, NY, USA

Synonyms

[N-Pthaloylglutamide](#)

Indications

Thalidomide is a potent teratogen.

Because of observed potential to increase tumor necrosis factor alpha production in vivo and interleukin-2 and interferon gamma in vivo, thalidomide has limited utility in the dermatologic manifestations of HIV, Behcet's disease, and graft-versus-host disease and is now being investigated for use in myelodysplastic disorders.

Mechanisms of Action

The teratogenic effect may be related to vascular disruption. As noted, it impacts immune function including increasing production of tumor necrosis factor alpha in vitro and interleukin-2 and interferon gamma in vivo.

Specific Compounds and Properties

The chemical name is *N*-pthaloylglutamide.

Clinical Use (Including Side Effects)

Thalidomide was initially developed in 1954 and licensed in 40 countries around the world for treatment of anxiety, insomnia, gastritis, and vomiting. It was marketed as safe for use in pregnancy. It was never approved by the Food and Drug Administration in the USA. By the early 1960s, increasing numbers of children were identified in Europe who were born with limb deformities. This, and eye movement abnormalities, was associated with thalidomide use by the mother between days 20 and 36 of pregnancy. Many years later, ophthalmologists Drs. Judy Miller and Kristen Stromland noticed that there was an increased rate of autism among individuals exposed to thalidomide in utero who were participating in their studies related to eye movement. This observation led to the association of autism with an environmental teratogen. Dr. Patricia Rodier worked out that this was likely to be due to impact on early development of the brain stem and resulted in her development of an animal model for early brain injury based on

valproic acid exposure since thalidomide has different toxicities in some animals.

The reasons why thalidomide is important in the study of autism include:

1. The impact on regulation and testing requirements for new medications brought to market regarding teratogenic potential
2. The association of autism with a known environmental toxin in a subgroup of affected individuals
3. The subsequent inquiry that led from early brain injury to investigation of early developmental genes as etiologic for autism

Theoretical Models and Autism

Nick Chown¹ and Luke Beardon²

¹Palau-solità i Plegamans, Lliçà de Vall, Barcelona, Spain

²The Autism Centre, Institute of Education, Sheffield Hallam University, Sheffield, South Yorkshire, UK

Definition

In this entry, the authors want to introduce you to some theoretical models of autism based on the

three main models of disability – the medical model, the social model, and the bio/psycho/social model – which we will review briefly first. But there are two terminology matters to consider before we begin. We explain why we use autism-first language in this entry. And we explain some terms introduced by Ian Hacking and Carol Thomas, an understanding of which is crucial to our discussion of the theoretical models.

We use autism-first language throughout this entry. That is because this form of language is generally preferred to person-first language by autistic adults. Although Dunn and Andrews argue that both forms should be used “to address the concerns of disability groups while promoting human dignity and maintaining scientific and professional rigor” (2015, p. 255), we are unaware of any evidence that respecting the views of the majority of autistic adults in this regard impacts adversely on scientific and professional rigor.

We also need to reflect on some terms introduced by Ian Hacking (1999) and Carol Thomas (1999, 2004) which form part of the framework of models. The terms we refer to are “indifferent kind” and “interactive kind” (Hacking) and “impairment effects” (Thomas). We also need to consider the essential differences between the main models of disability, i.e., the medical, social, and bio/psycho/social models. Those who regard autism as cognitive, perceptual, and sensory difference object to the term “impairment.” They would presumably also object to the term “impairment effects.” We use this term in our framework of autism models for the same reason Thomas introduced it, to distinguish between the inherent effects of an impairment and the additional, avoidable, societal effects. Those who agree with us that autism involves a set of *differences* (we do not subscribe to the view that all autistic individuals are inherently *impaired*) could substitute “difference effects” or “inherent disadvantages” for “impairment effects.”

In *The Social Construction of What?* Hacking (1999) discusses the increasingly widespread use of the concept of social construction and of things being socially constructed using examples such as authorship, the child viewer of television, danger, emotions, gender, and illness. He argues that in many cases it is only superficially correct to

refer to something as being socially constructed since every concept people invent is socially constructed in the trivial sense that all human concepts are the result of social interaction. The two terms he has introduced are designed to highlight the distinction between the kind of things that can interact with the people who are of that kind and those things that do not interact in that way; the former falling into the category of “interactive kind,” and the latter in the category of “indifferent kind.” Examples should make the difference clear. Hacking uses the concept of the “woman refugee” to explicate the idea of an interactive kind; the important point here being that when a woman knows that she is classified as a “woman refugee” she may, unknowingly or not, begin to act *as* a woman refugee, that is, behaving in ways she would not if unaware of her classification. In the same way, an autistic person may start analyzing their behavior after receiving a diagnosis of autism, explaining past behavior from the perspective of autism, and perhaps being less likely to mimic nonautistic behavior (especially in a setting where autism is accepted as natural human difference). Thus, a diagnosis of autism may interact with the individual diagnosed to change behavior and is, therefore, an interactive kind. The opposite of an interactive kind is an indifferent kind where no interaction effect between the concept and the thing itself is possible. For instance, to use a couple of Hacking’s examples, neither quarks nor microbes, even though the latter interacts with human beings, are aware of what they do and so are said to be indifferent to their classification as quarks and microbes (we think that “unaware” would have been a better choice of term as “indifferent” implies the holding of a view by a thinking being). Likewise, a cognitive difference in autism is indifferent to, or unaware of, its status as a cognitive difference prior to the autism being identified and understanding of the difference having developed.

Much has been written about disability models. We only have space to draw attention to the fundamental difference between the medical model of disability and the social model of disability and position the bio/psycho/social model. While the medical model places the “fault” for being

disabled fairly and squarely with the individual, under the social model disability is seen as the result of attitudes and barriers imposed by society over and above an individual’s impairments. Unlike the other two models, the bio/psycho/social model acknowledges biological, psychological, and social disabling/disadvantaging effects.

Realizing that not all disabling effects are the fault of society, Thomas introduced the term “impairment effects” to enable a distinction to be drawn between the inherently disabling effects of a perceived impairment and the effects of the attitudinal and physical barriers placed in the way of individuals with impairments by society. In the context of autism one might want to say, for example, that the difficulties arising from sensory sensitivities may not always be something that society can do anything to ameliorate. But failure to appreciate the strengths in autism, and enable an individual to make the most of those strengths, is a barrier that society should work to remove.

Historical Background

We now introduce the medical, social, and bio/psycho/social models of disability before considering autism from the perspectives of these three models, comparing the perspectives, and drawing some conclusions.

Medical Model of Disability

The historical background here is that autism, inevitably because it relates to a series of medical diagnoses beginning with “infantile autism” in the ninth revision of the World Health Organization’s International Classification of Diseases (ICD-9) published in 1979, and a year later in the third edition of the American Psychiatric Association’s Diagnostic and Statistical Manual (DSM-III), has been seen through the lens of the medical model of disability (also known as the individual model). The medical model of disability has been described by a Cerebral Palsy group as:

a model by which disability is the result of a physical condition, is intrinsic to the individual (it is part of that individuals own body), may reduce the individuals quality of life, and causes clear

disadvantages to the individual. By this model, a compassionate or just society should invest resources to attempt to cure disabilities medically or to improve functioning

(<http://www.livingwithcerebralspalsy.com/social-disability.php>)

The main criticism of the medical model of disability is that it equates disability solely with impairment, ignoring the involvement of social, cultural, and environmental factors in the construction of disability. The medical model has been said to attach blame to the individual for their disability and in that respect it is, at least, consistent with what Reindal refers to as the “many historical examples of individualising social problems: explaining poverty and unemployment as a result of idleness and character weakness; crime as a result of ‘moral insanity’” (Reindal 2008, p. 141). In this context, with disability being seen as the fault of the disabled person, society has little or no responsibility for looking after them, let alone for implementing change in order to reduce the impacts of societal barriers (because there is no recognition of the barrier concept). Over time, societal attitudes began to change and disability was increasingly seen as a personal tragedy for the “unfortunate individual with impairments.” As Reindal writes, “This approach . . . promoted attitudes of paternalism and mechanisms of dependency . . . within society” (Reindal 2008, p. 141) which led to a more caring or charitable attitude towards disabled people, but still with no acknowledgment that society was itself the primary cause of disability.

Social Model of Disability

A great deal remains to be done to ensure that people with disabilities are enabled to take their rightful places as full-fledged citizens within society, there is still much lip service paid to antidiscrimination, and the practice of “exclusion through nominal inclusion” (Thomas 2006, p. 177) is, perhaps, more prevalent than substantive inclusion. However, the advent of the social model of disability in the mid-1970s has had a profound impact on disability advocacy and

outcomes since its development through the work of the Union of the Physically Impaired Against Segregation (UPIAS), including the disabled scholar and activist Michael Oliver. The Cerebral Palsy group referred to in relation to the medical model of disability describe the social model of disability as follows:

the ‘social model’ of disability, makes a clear distinction between the impairment itself (such as a medical condition that makes a person unable to walk) and the disabling effects of society in relation to that impairment. In simple terms, it is not the inability to walk that prevents a person entering a building unaided but the existence of stairs that are inaccessible to a wheelchair-user. In other words, ‘disability’ is socially constructed.

(<http://www.livingwithcerebralspalsy.com/social-disability.php>)

While it is probably true to state that there is more rhetoric from organizations claiming to apply the principles of the social model of disability than actual application of those principles, even critics of the social model must accept that its development and increasing level of adoption has led to major benefits for disabled people. With eminent justification, this model is often referred to as the “big idea” of the disability movement.

Bio/Psycho/Social Model of Disability

The International Classification of Functioning Disability and Health (ICF) is the framework developed by the World Health Organization (WHO) for measuring health and disability at both individual and population levels. It was officially endorsed by all 191 WHO Member States at the 54th World Health Assembly held on 22 May 2001. The ICF is a classification of health and health-related domains based on bodily, individual, societal, and environmental perspectives through placing individuals on lists of bodily functions, activity limitations, and environmental factors. The ICF is said to complement the ICD diagnostic manual, referred to earlier, which comprises a classification of diagnoses based on etiology. The WHO has written that:

The ICF puts the notions of ‘health’ and ‘disability’ in a new light. It acknowledges that every human being can experience a decrement in health and

thereby experience some degree of disability. Disability is not something that only happens to a minority of humanity. The ICF thus ‘mainstreams’ the experience of disability and recognises it as a universal human experience. By shifting the focus from cause to impact it places all health conditions on an equal footing allowing them to be compared using a common metric – the ruler of health and disability. Furthermore ICF takes into account the social aspects of disability and does not see disability only as a ‘medical’ or ‘biological’ dysfunction.

https://ec.europa.eu/eip/ageing/standards/healthcare/e-health/icf-browser_en

The WHO regard the ICF as following what they call a biopsychosocial model of disability that “synthesizes what is true in the medical and social models, without making the mistake each makes in reducing the whole, complex notion of disability to one of its aspects” (WHO, p. 9). Reindal writes that the understanding of disability within the ICF is about restricted activities and an inability to do things that others can do, that it “is a weaker framework for theorising about empowerment and autonomy for disabled people, as goals for participation rest on norms related to normality” (Reindal 2008, p. 138) and, perhaps most important of all given the importance of oppression to the founders of the social model, the issue of oppression is lost in Reindal’s view.

Current Knowledge: Theoretical Models of Autism and Autism Theory

We aim to explain the five elements of a proposed framework of models of autism (see Table 1), which could also be described as a framework of perspectives on autism from which autism theory – which we discuss in a separate entry – can be viewed. These perspectives include one in which autism is regarded as nothing more than a label applied by classificatory systems to something that is a reified category with no existence other than as a conglomeration of unconnected behaviors (i.e., it is entirely socially constructed). The other four perspectives regard autism as something “real” in that it has a biological/neurological cause, at least in part, as well as socially constructed aspects. The opposite of the “denial”

Theoretical Models and Autism, Table 1 A framework of perspectives on autism (autism models)

Category	Kind	Cause
1. Autism as nothing more than a label – social model		
Diagnosis (label)	Interactive kind	Socially constructed
2. Autism as cognitive/perceptual/sensory difference – social model		
Differences	Indifferent kind	Bio/psycho causation
Societal effects pre-diagnosis	Indifferent kind	Socially constructed
Societal effects post-diagnosis	Interactive kind	Socially constructed
Diagnosis ^a (label)	Interactive kind	Socially constructed
3. Autism as disability in a lay sense – social model		
Impairments	Indifferent kind	Bio/psycho causation
Impairment effects	Indifferent kind	Bio/psycho causation
Disability (societal effects) prediagnosis	Indifferent kind	Socially constructed
Disability (societal effects) postdiagnosis	Interactive kind	Socially constructed
Diagnosis (label)	Interactive kind	Socially constructed
4. Autism as disability in a lay sense – bio/psycho/social model		
Impairments	Indifferent kind	Bio/psycho causation
Impairment effects	Indifferent kind	Bio/psycho causation
Societal effects pre-diagnosis	Indifferent kind	Socially constructed
Societal effects post-diagnosis	Interactive kind	Socially constructed
Diagnosis (label)	Interactive kind	Socially constructed
5. Autism as disability in a lay sense – medical model		
Impairments	Indifferent kind	Bio/psycho causation
Disability	Indifferent kind	Bio/psycho causation
Societal effects pre-diagnosis ^b	Indifferent kind	Socially constructed
Societal effects post-diagnosis ^b	Interactive kind	Socially constructed
Diagnosis (label)	Interactive kind	Socially constructed

^aThose who see autism as a set of differences do not consider that it should be included in diagnostic manuals
^bSeemingly unacknowledged societal effects

of those who consider autism to be no more than a label is the medical model perspective whereby autism is generally considered to be entirely biological/neurological in nature. However, in our view, even a medical model perspective on autism should incorporate socially constructed elements as we hope to make clear. We now consider each of the five sections of our framework of perspectives on autism.

We understand why Runswick-Cole (2016, p. 27, our italics) writes that it would be far better to have a support service for people currently labeled with autism “that labels people, *but only with their names*.” She stresses the importance of practitioners asking questions about a person rather than a disorder and offering to help them achieve their aspirations “rather than intervening to ‘correct’ perceived symptoms and deficits.” We agree with Runswick-Cole that it is essential to consider an individual’s unique needs, especially as the effects of autism vary so greatly. It is also unarguable that the label of autism is generally needed to enable access to support where it is available. However, although some scholars may consider dispensing with this label to be a valid longer-term objective, we disagree, as the label has helped many autistic individuals to achieve a better understanding of themselves. There are even, as Goodley (2016, p. 147) points out, those who “have suggested that autism is nothing more than a myth perpetuated by the biopolitics of psychiatry and psychology.” This is not the place to mount a challenge to those who believe autism is *only* a label. However, holding this view is to be utterly dismissive of leading clinical expertise beginning with Asperger and Kanner, the experiences of those for whom becoming aware that they are autistic has been transformational, and the experiences of parents of autistic children.

We now move on to consider the other elements of the framework: autism as cognitive/perceptual/sensory difference, and as disability, from the perspectives of the three main disability models: the medical model, social model, and bio/psycho/social model. Members of the general public would usually regard autism as a disability in the sense of being something inherent in the individual that has an adverse effect on their

ability to function in society to the fullest extent (though it should be noted that such judgements are made from a predominant neurotype (nonautistic) perspective and, therefore, may not be valid for all autistic individuals). This lay understanding of disability contrasts with the social model perspective on disability as attitudinal and physical barriers socially constructed by society in addition to impairments/differences. Whether understood as impairments or differences, matters caused biologically/neurologically are indifferent kinds according to Hacking’s definition because there is no interaction effect between them and the individual autistic person; the impairments/differences are simply what they are. We think that the societal effects are also indifferent kinds prior to receipt of a diagnosis – because at this stage they cannot interact with the individual and change behavior – but may transform into interactive kinds after diagnosis when the diagnosed individual becomes aware of them and reflects on their effects on him or her. Even in the case of the model regarding autism as nothing more than a label, we are in no doubt that a diagnosis is an interactive kind because it can interact with the individual and thus carries the potential to change behavior.

We argue that autism involves impairments/differences, impairment effects as understood by Thomas, and societal effects. The social difficulties and sensory sensitivities in autism may have disabling effects to which society adds a layer of attitudinal and physical barriers that further disable. Although the medical model regards autism as a set of impairments that themselves disable an individual, it seems to us that those who adopt a medical model perspective should acknowledge that societal effects do exist; those who consider that impairments result in disability should accept that impairments do not cause disabling attitudinal and physical barriers. Ignoring the label-only model, there is little difference between the models. In each case, there are impairments/differences (which may disadvantage), impairment effects, an overlay of disabling societal effects, and the potential for behavior change following receipt of a diagnosis.

When seemingly unacknowledged societal effects are included in a medical model

perspective, the result is not unlike a bio/psycho/social model. If a social model perspective does not ignore impairments/differences, and the impairment effects Thomas wrote of, it is also virtually indistinguishable from a bio/psycho/social model. We do not consider that rejection of a medical model perspective on autism of necessity requires autism to be viewed as a social construct in a nontrivial sense as Shyman (2015, p. 73) appears to believe having written that “the medical model of viewing autism is overtly rejected in favor of viewing it as a social construct.” [In a trivial sense, autism and every other diagnosis, together with the diagnostic manuals themselves, and the psychiatry and psychology that led to the development of these manuals, are socially constructed.] We argue that it is the idea of autism *as a disorder* that is socially constructed in a nontrivial sense and that medical diagnosis would not be as necessary as it is currently if society accommodated the differences in autism, while stressing the importance of identifying individuals who are autistic. Formal *identification* (diagnosis) of autism is essential to: (1) help autistic individuals to better understand themselves; (2) assist those who live and work with autistic people to support them; and (3) enable the authorities to implement ad hoc environmental adaptations for those who need them. To be clear, we are saying no more than that it is wrong to medicalize a set of cognitive, perceptual, and sensory differences. We do not deny the effects autism can have on the lives of individuals and their families/carers. Neither do we challenge the role of clinicians in relation to autism while it remains necessary for individuals to be diagnosed as autistic to secure protection under disability discrimination legislation (such as the UK’s Equality Act, 2010) and access to whatever local authority support is available.

Future Directions: For Autism Research

Irrespective of an individual’s perspective on autism, especially given our view that there is less difference between the three main models of disability than there may appear to be, many

members of a sizeable community of autistic people need support. This section is a combination of a reflection on the Pellicano et al. paper (2014) alongside a summary of our rationale for certain types of research being more advantageous than others because of our belief that research in autism should be focused primarily on supporting individuals with cognitive, perceptual, and sensory differences to achieve the fullest life possible in every respect (education, relationships, work, etc.). Pellicano and colleagues identified the following six types of funded autism research over a 3-year period specific to the UK (along with the percentage of funding allocated to each type of research over those 3 years):

1. Biology, brain, and cognition – 56%
2. Treatment and interventions – 18%
3. Causes – 15%
4. Diagnosis, symptoms, and behaviors – 5%
5. Services – 5%
6. Societal issues – 1%

The reaction from the autism community was almost entirely negative, with autistic adults suggesting that research follows a nonautistic agenda, and parents reflecting that research fails to accurately reflect the reality of the lived experience of autistic individuals. It is not possible to simply identify what is “good” research and what is “bad” research in terms of type, but it is worth identifying questions that might enable researchers to ascertain the purpose of their research and what potential impact it might have. This, in turn, might enable funders to understand the efficacy and purpose of research aims. We suggest the following questions provide a structure within which research can be framed:

1. Does the research engage directly with the autism community?
2. Does the research engage with autistic individuals as “subjects” or as co-researchers?
3. What potential impact might the research have on autistic individuals?
4. What impact might the research have on those associated with autism (e.g., parents, carers, professionals)?

5. Is the main purpose of the research to directly or indirectly influence quality of life for the autistic population?
6. Does the research intend to establish new knowledge that can influence practice that will have a positive influence within the autism community?
7. How might the research enable practitioners to develop better practice?
8. How involved are autistic people in the aims of the research and the project design?
9. Does the research fulfil or acknowledge any criteria identified by the autism community as needing investigation?

Clearly this list of questions is not exhaustive, but it does provide a structure within which the purpose of research and its potential links to practice can be explored. Chown et al. (2017) have developed a more detailed framework of criteria for what they refer to as “inclusive” autism research, i.e., research which is both emancipatory and participatory. Neither we nor they dismiss research that may not influence the day-to-day lived experience of autistic individuals entirely; however, it is acknowledged that the current funding of autism research does not reflect the views of the autism community and we suggest that this needs addressing as a matter of urgency.

Theories of Language Development

Inge-Marie Eigsti
Department of Psychological Sciences,
University of Connecticut, Storrs, CT, USA

Definition

Language acquisition presents children with a tremendous challenge: how to determine the mappings between meanings in their world, and the complex acoustic signal of speech. Children must segment the running stream of sounds that they hear into words and phrases, and determine the regularities, or systematicities, of the language. Furthermore, they accomplish this task in the absence of direct instruction and even (for example, in the case of Quiche Mayan) while hearing little language directed at themselves (Pye 1986). As such, the acquisition of human language has been described as the single most impressive

intellectual accomplishment of individual humans (Pinker 1984).

There are five systematic features of language that a learner must master in order to understand and produce a spoken or signed language. Note that while this review focuses on spoken languages, there is such significant overlap with signed languages; see the ► [“American Sign Language \(ASL\)”](#) entry for more information. *First*, they must learn the phonology – that is, the inventory of sounds that make up the language. Sounds are considered to be distinct phonemes when they are “minimally contrastive,” such that two words which differ only by that sound, are recognized as distinct words (“*pin*” vs. “*pen*” is a minimal pair in English, whereas “*pint*” vs. “*pint^h*” with a final “*t*” accompanied by a puff of air is noncontrastive). Children learning English must master an inventory of 12 distinct vowels and 24 consonants (depending on their dialect); classical Arabic, 6 vowels and 30 consonants; and Swedish, 17 vowels and 18 consonants. The phonology of a language corresponds to a degree to its written alphabet, but is not identical (and indeed, in English, the alphabet/phonology correspondence is particularly weak, making the acquisition of reading in English a particularly lengthy and error-prone process).

Second, the learner must learn an inventory of words; that is, she must determine what concepts are encoded as words, and map those concepts onto specific sequences of sounds. The acquisition of a language’s vocabulary, or *lexicon*, is a challenging proposition; some languages convey concepts that, in other languages, are unspecified (for example, the concepts *melancholy* and *gloomy* are conveyed by a single term in many other languages). Typically developing children produce first words by around 10–11 months. These early words generally consist of names for specific individuals (*mama*, *Sarah*), objects (*dog*, *banana*), or substances (*juice*); other early emerging word types include action verbs (*give*), adjectives (*pretty*), and some social expressions (*hi*, *no*). Abstract terms, such as mental state verbs (*think*, *remember*), and those expressing nonpresent objects or events, are produced later. Children bring a set of useful constraints or biases to this learning problem;

for example, they are guided by an assumption of “mutual exclusivity,” which suggests that novel concepts should be expressed using novel words (Markman 1990). Research indicates that children with autism spectrum disorder share at least some of these important biases (e.g., mutual exclusivity; de Marchena et al. 2011), but not all (e.g., the shape bias; Tek et al. 2008).

Third, the learner must determine how words are meaningfully combined in the language, a system of combinatorial rules known as syntax (also called grammar). In English, a descriptive noun phrase might consist of a determiner (e.g., *the*), an adjective (*fuzzy*), and a noun (*rabbit*); sentences in English are structured as subject-verb-object. During the second and third years of life, children’s utterances increase in length and complexity, and increasingly incorporate function words (*if*, *the*, *over*); they also incorporate advanced syntactic devices such as relative clauses (*the cookie that I ate yesterday*), yes/no questions (*can I have that cookie?*), and if/then statements (*if I eat my dinner, can I have a cookie?*).

Fourth, children must learn how to mark tense, gender, number, aspect, register (formality or politeness), and so on, via either phrasal combinations or via morphological markers. “Morphemes” are the smallest meaningful units of language; morphological development refers to the development and understanding of these units and how such units are combined into words. For example, *junper*, *jumped*, *jumps*, and *jumpy*, all use the morpheme “*jump*” in combination with morphemes *-er*, *-ed*, *-s*, and *-y*. In many languages (typically those where word order is free to vary), syntactic information is conveyed primarily through morphological markers; thus, many theories of language structure collapse morphology and syntax into a single process (morphosyntax).

Finally, in addition to phonological, lexical, morphological, and syntactic development, children must learn to use language as a social tool. Pragmatic language refers to a speaker’s ability to select of words that are appropriate to the social context (“register,” i.e., speaking more formally to a professor than to a peer, avoiding taboo words in many situations); negotiating when it is one’s turn in the conversation; the choice of referential expressions

(*a* vs. *the*); use of indirect speech (*it's very cold in here*), sarcasm (*nice shirt, Mom*), or metaphor (*you had that one hidden up your sleeve*); repair of miscommunications; the use of prosody (the melody or rhythm of the voice); the use of perspective in language (*he thought that she was going home*); and nonverbal linguistic functions (e.g., eye contact, body language, and gestures). Discourse is a closely related concept, which refers to the production of longer connected streams of speech, as in the telling of a story or joke. Narrative ability is important for communication as well as for the structuring of one's own thoughts.

Historical Background

According to Herodotus (Fromkin et al. 1974), an Egyptian pharaoh, Psammetichus the First, conducted one of the first known experiments on language acquisition. Hoping to uncover the “original” language, he caused two newborn babies to be left with an isolated shepherd, who was ordered not to speak with them. The shepherd monitored their speech sounds; as the first word uttered sounded like “bread” spoken in Phrygian, Psammetichus concluded that Phrygian was the original or primary language of the world. Later work has also attempted to build on the experiences of feral or wild-reared children in order to explore the process of language acquisition in the absence of or given inadequate language input (Candland 1993); one challenge is to disentangle language input from atypical social experiences.

Another classic formulation described in theories of language acquisition is a problem posed by the philosopher Quine, commonly known as the “gavagai” thought experiment (Quine 1960). Quine asks us to imagine standing in an alien world, next to a native from that world; when a rabbit runs past, the native points and says, “gavagai!” While *gavagai* might refer to the concept *rabbit*, there is a nearly infinite number of alternative interpretations, such as *brown*, *furry*, *four-legged*, *speedy*, *hopping*, *delicious*, *watch out!* or, even, *an assembly of rabbit parts*. How can a learner determine what semantic concepts

are conveyed, when they happen to hear an isolated word spoken?

Faced with the challenges of learning what sounds should cohere to form words, the challenge of determining word meanings, and the challenge of learning how words should be further combined, one might assume that an important component of language acquisition is the instruction of adults. Indeed, a typical educated parent in the USA may act according to the assumption that she is teaching her infant to speak. Somewhat surprisingly, however, children receive very little explicit instruction in their language; what is more, they appear to receive little negative (error-correcting) feedback about their own speech. That is, when children produce a speech error, it is rarely explicitly corrected. Furthermore, children are famously resistant to such corrections. McNeill reports a now-famous anecdote about this resistance to error correction (McNeill 1970, p. 106): Child: *Nobody don't like me*. Mother: *No, say “nobody likes me.”* Child: *Nobody don't like me* (eight repetitions). Mother: *Listen carefully: say, “nobody likes me.”* Child: *Oh! Nobody don't likes me*.

Current Knowledge

As reviewed above, the challenge of learning a language is a formidable one. Given the difficulties, it is remarkable how uniform the process of acquisition is. It follows a similar developmental progression across children, despite quite striking differences in the structure of the language being learned, culture, individual differences in intelligence or sociability, parent factors, and so on. That said, however, not all children develop functional language skills; in addition to the clinical implications of this fact, the study of delays and deficits in acquisition can help to elucidate the nature of the language acquisition process, by throwing into sharper relief the developmental course of language acquisition (Cicchetti and Rogosch 1996; Curtiss et al. 1992).

One of the primary theories of language acquisition is associated with “nativist” approaches to human development. The enormous complexity

of language, and the relatively limited direct “teaching” of language (along with the uniformity of acquisition of language milestones), has led scholars in the nativist or innate school to propose that language development proceeds according to the growth or unfolding of an innate language faculty, just as physical development proceeds in the absence of specific instruction or special input (e.g., Chomsky 1986; Fodor 1983). Chomsky formulated one of the most influential theories of language that applies to the nativist approach, the principles and parameters framework (and its subsequent iterations and revisions, Government and Binding, and the Minimalist approach). In this model, humans have innately specified knowledge about language: a set of principles shared by all human languages (e.g., that all grammatical sentences must have a (possibly covert) subject) and a set of parameters that specify how a given language instantiates specific syntactic qualities (e.g., that the subject should be overtly expressed, or not); parameters are essentially binary decision processes. Under this account, children require little language input; they only require enough input to direct them in how to set those particular parameters.

The “constructionist” perspective provides an alternative perspective (see Elman et al. 1996); in this account, general and nonlinguistic learning capacities may account for much or all of language knowledge. Although support for related theoretical positions dwindled after Chomsky’s (1959) influential and overwhelming critique of behaviorism, more recent research suggests an important role for domain-general learning capacities such as tracking the statistics of words or sounds in language input (Saffran et al. 1996). The history of research in language development has been marked by disagreement between the nativist and constructionist positions; currently, many researchers in the field accept some middle ground between the strict nativist and the purely empiricist approaches, suggesting that children may draw on some innately specified biases as well as on domain-general learning processes.

There are several important models that fall in the middle ground of, or otherwise negotiate between, the nativist and empiricist perspectives.

One usage-based account, the “verb island” hypothesis (Tomasello 2000), for example, suggests that children acquire syntactic knowledge gradually, item by item, and that much of their early knowledge consists of memorized two- or three-word structures (with relatively little transfer of morphological structure across verbs). Experiments presenting children with novel (nonsense) verbs indicate a sharp change between ages 3 and 4. Specifically, children aged 3–4 are able to extend novel verbs to abstract syntactic categories; for example, they are able to use a verb heard only in a passive sentence frame and utilize it in an active sentence frame. However, children aged 2–3 years have difficulty extending verbs between transitive and intransitive frames.

Connectionist approaches to acquisition have also provided a set of tools for addressing the trade-off between the apparent poverty of syntactic input to the learner (i.e., the “learnability” problem) and the role of innate structures and processes in development; thus, while often described as simply a version of empiricism, connectionism and empiricism are not necessarily identical (Plunkett 1997). “Connectionism” refers to computational models (either theoretical or actually implemented using computer learning algorithms) that take input (typically, somewhat abstracted in nature from actual language input) and feeds that input forward (e.g., through a single layer of units or nodes) to a set of output units. For example, a network model of past tense formation in English might receive as input an abstracted phonological representation of the verb stem (*jump*, *swim*); activation (i.e., which units are ready to “fire” at a given time) passes from input units to a connected set of output units; those units receiving the strongest input activations are most likely to be active in the output (e.g., the corresponding past tense form: *jumped*, *swam*). The output activations are compared to the target activation pattern (e.g., the correct past tense form), and any discrepancies form an error signal which influences the network connections. Connectionist models have helped demonstrate “proof of principle” that a single learning system is capable of generating such apparently distinct outputs as the regular past tense form (*-ed*) along

with the irregular forms. Connectionist models have also helped to generate and test models of concept formation and vocabulary acquisition (see Plunkett 1997). Work of the past decade has examined children's ability to make use of distributional aspects of language input (e.g., Saffran et al. 2007) and demonstrated both the availability of potentially informative information in the statistics of language input, as well as learners' ability to access that information. Few computational models of ASD have been formulated (though see, e.g., McClelland 2000), though this approach may increasingly offer researchers ways to develop and test hypotheses about human acquisition.

Among the many methodological innovations in child language research, several bear particular mention: the language database approach. Research in this field has often made use of "diary studies" in which investigators track the spontaneous utterances produced by an individual child over time. This is a valuable resource for that individual, but it becomes a highly useful resource if it is available to others. The CHILDES website project has assembled written transcripts of children's speech from 34 languages, several clinical populations, and children in bilingual acquisition contexts. This publicly available, searchable, and downloadable database has been used as a resource in more than 3,000 publications from its inception through 2008. It can be accessed at <http://childes.psy.cmu.edu/>. MacWhinney, who is the principal investigator on the CHILDES database, spearheaded the development of a language transcription system (CLAN), also available on that website.

Another recent innovation in child language research is the availability of the LENA (Language ENvironment Analysis) system. A small recorder, generally worn as a backpack, can record a child's voice as well as other voices and sounds in the child's environment, across varied settings (home, playground, preschool, therapy sessions, etc.). After recording, software algorithms are able to automatically tag each speech sound according to its sound source (adult, child, male, female, etc.), and to label them as speech or nonspeech (Oller et al. 2010). While the LENA system does not lend itself to fine-grained analyses of specific narrow aspects of acquisition, it permits researchers

to collect large corpora from large groups of participants (e.g., Warlaumont et al. 2014).

Future Directions

Researchers in the field of language acquisition have often turned to ASD as a sort of "natural laboratory" in which to test theories of acquisition because studies of this disorder offer the possibility of examining meaningful differences in ability across a wide range of language, social, and cognitive domains. At the same time, research in this area must grapple with the subtleties in performance and ability that are part and parcel of a developmental disorder; development is rarely as neatly "packaged" as we might hope. For example, in typical development, comprehension seems to outpace production in early language acquisition; thus, children who do not produce function words (e.g., determiners) show effects in comprehension and memory when those elements are left out, suggesting some sensitivity and awareness of these elements. Children with ASD appear to provide a distinct picture, with some data suggesting that their production may outpace their comprehension. Research in the field must reconcile this somewhat bewildering inconsistency with a finding in typical development that is, as yet, unexplained. Open questions remain about acquisition in autism remain to be addressed, using cross-linguistic studies (e.g., Brynskov et al. 2017), eyetracking (e.g., Schuh et al. 2016), and psychophysiological tools such as EEG and MRI, among others.

Theory of Mind

Coralie Chevallier

SGDP Centre, Institute of Psychiatry, King's College, London, UK

Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, USA

Definition

Theory of mind (ToM) refers to the capacity to attribute mental states to others and oneself in order to explain and predict behavior. ToM is an evolved psychological ability, most highly developed in humans, specialized in the rapid attribution of beliefs, intentions, desires, or knowledge to others and oneself and in the spontaneous understanding that others have mental states that may differ from one's own.

The attribution of mental states to others pervades human cognition. When watching others, we automatically interpret their current behavior in the light of the intentions they might have. If we

see a man running as a bus passes by, for example, we will be inclined to explain his behavior by the fact that he *intends* to catch the bus, and this will lead us to predict that he will hop on the bus if he does manage to get to the bus stop in time. Attributing mental states and predicting behavior on that basis can thus be seen as our most natural way to grasp the social world.

Historical Background

Historically, the false belief task was considered to be the best test of ToM abilities: passing the test meant that one was able to represent others' mental states and failing the test was taken as evidence that one was impaired representing others' mental states. In false belief tasks, the participant is typically put in a position where she needs to take someone's belief into account so as to provide the appropriate answer to a question. Crucially, the belief she needs to take into account differs from her own (hence the term "false" belief). Standard false belief tasks have led to an industry of studies among which the unexpected location task is most common. In the "Sally-Anne" paradigm (the initial version of the unexpected location task), the location of an object is changed in the absence of a character who then has to look for the object. Children are told a story involving two dolls, Sally and Anne, playing with a marble. Sally puts the marble away in a basket and leaves the room. In Sally's absence, Anne takes the marble out and plays with it. Once she has finished playing, she puts the marble away in a box. Sally returns and the child is asked where Sally will look for the marble. The child passes the task if she answers that Sally will look where she first put the marble; the child fails the task if she answers that Sally will look in the box (where the marble really is) (for descriptions of other similar tasks, see Baron-Cohen 1995).

Using these types of tasks, a substantive body of research led to the following threefold conclusion: (1) ToM is specifically human and does not appear to be part of other animals' psychological makeup (including nonhuman primates),

(2) typically developing children master ToM types of reasoning from around the age of four and rarely succeed in false belief tasks before that age (for a recent review see, Wellman et al. 2001), and (3) individuals on the autism spectrum face important difficulties with false belief tasks, which can be taken as evidence of a specific ToM impairment in the condition (Baron-Cohen 1995). Over the past decade, however, each of these conclusions has been challenged and current knowledge about ToM in typical and atypical development has been considerably reviewed as a result.

Current Knowledge

A considerable amount of recent research has aimed to elucidate the phylogenetic and ontogenetic roots of ToM and findings emanating from these fields of research are especially relevant to better understand the consequences of ToM dysfunctions in autism spectrum disorders (ASDs).

Philogeny. For a long time, ToM was construed as a uniquely human feature, and even our nearest relatives were thought to be unable to understand the psychological states of others. It was agreed that they could understand others' behaviors, but they were thought to do so using a behaviorist rather than a mentalistic stance. This view, however, was recently challenged by a number of findings suggesting that apes are not fully blind to others' mental states. In experimental settings, there is now robust evidence that chimpanzees are able to grasp actions underlying goals and intentions and that they understand that others perceive the world in a way that may differ from their own.

Evidence that chimpanzees understand the actions of others not just in terms of behaviors but also in terms of goals and intentions include the fact that they react differently when facing an actor who is unwilling versus unable to give them food, that they distinguish accidental and intentional behaviors, and that they are able to imitate the intended goal of an action even when the demonstrator failed to achieve that goal (for a review of 10 relevant studies, see Call and

Tomasello 2008). Evidence that chimpanzees are sensitive to others' perceptions include chimps' ability to follow the gaze of others (and the associated expectation that something relevant should be found at the target location), their understanding that gaze is stopped by opaque occluders, their use of gestures restricted to contexts when they know that others see and attend to what they are doing, and their use of all that knowledge for food competition purposes (i.e., pick the food that others are not looking at or cannot see because of an occluder) (for a review of 16 relevant studies, see Call & Tomasello).

Whether these skills are indicative of true ToM is still hotly disputed. In particular, evidence that chimpanzees are able to understand *beliefs* is still lacking. To date, every attempt at demonstrating that chimpanzees can succeed in understanding false beliefs, considered to be the only acid test of ToM, has failed.

To conclude, though evidence for fully human-like ToM is lacking, recent research now unambiguously indicates that chimpanzees do much more than simply reading overt behavior: they understand goals, intentions, perceptions, and knowledge of others and use these mentalistic mechanisms to make sense of and predict other's behaviors.

Ontogeny. Much research has investigated the early precursors to the development of a fully functional ToM, such as gaze following, perspective taking, or goal attribution, which all develop within the first 1 or 2 years of life. Infants start following the gaze of others as early as 3–6 months and use pointing gestures by around 1 year. Infants also demonstrate an early ability to take the perspective of others and make inferences regarding what others can see and cannot see. For instance, they know that one cannot see a target with closed eyes or under a blindfold. Infants as young as 14 months also take into account various kinds of obstacles in determining what others can see. In particular, they understand that an opaque screen blocks people's vision or that an adult looking behind a barrier can see things that they cannot see (Tomasello 2008).

Infants are also able to attribute goals to agents from about 7 to 12 months of age. For instance, in a well-known series of habituation studies, Csibra, Gergely, and colleagues demonstrated how infants interpret an agent's behavior in the light of the rational goal she might be pursuing (many relevant papers are available on Gergely Csibra's website). In the classic study, infants are habituated to a large dot jumping over an obstacle and approaching a small dot. When the obstacle is removed, infants are surprised if the large dot continues to jump while approaching the small dot (despite the fact that the path of movement is identical to the one they had been habituated to). However, if the large dot stops jumping and goes straight to the small dot, infants are not surprised (despite the fact that the path of movement differs from the one the infant has been habituated to). These results are evidence in favor of the idea that infants are able to attribute goals to moving agents. These behaviors (e.g., gaze and point following, perspective taking, goal attribution, etc.) all appear within the first 2 years of life and constitute early manifestations of our innate ability to understand mental states.

As far as the understanding of beliefs is concerned, the consensual view was that it emerged later on in development, at around the age of 4. Over the past few years, however, new paradigms have demonstrated that reasoning about beliefs can appear much earlier in development than previously taught. For instance, infants as young as 15 months old or even 13 months old are surprised when the actor's behavior does not match her true or false belief regarding the situation. In one experiment, for example, the infant sees an agent take a toy out of one of two boxes. The toy is then moved from one box to the other, either in the presence of the agent (true belief condition) or in her absence (false belief condition). The infant then sees the agent reach for the toy in one of the two boxes. Infants' looking times are used to measure their degree of surprise. Results indicate that infants look significantly longer when the agent's behavior is incongruent rather than congruent with her false belief (i.e., when she reaches for the box containing the toy) (Baillargeon et al. 2010).

Evidence in favor of early ToM skills is also compatible with a wealth of research in developmental pragmatics indicating that preverbal infants are able to engage in inferential communication that requires taking the audience's perspective. For instance, much research demonstrates that young children's pointing behaviors are best understood by positing that they are in some sense trying to influence the audience's mental states. Infants as young as 12 months spontaneously point to help an adult by providing her with needed or desirable information (Tomasello 2008). Conversely, infants are able to interpret adults' points and gaze direction as cues to their communicative intentions. In particular, infants use these behaviors in word-learning situations as crucial cues to the speaker's referential intent (Bloom 2000). Moreover, recent experiments demonstrate that 2–4-year-olds do not blindly follow gaze (or points), but consider the linguistic and pragmatic context when learning a new word. More strikingly still, recent research demonstrates that manipulating whether or not a communicator has a false belief leads toddlers to different interpretations of the same communicative act, thereby demonstrating early mental state attribution in pragmatic contexts (Baillargeon et al. 2010).

Taken together, these results indicate that infants with very limited verbal abilities understand goals, intentions, and even beliefs. This suggests that ToM is an essential part of our psychological makeup and confirms that there is a strong innate component to ToM.

ToM Dysfunction in Autism Spectrum Disorders. Among the various cognitive accounts of autism, the hypothesis of a primary deficit in ToM has had a considerable influence in both psychology research and intervention strategies. In this framework, an impaired ability to understand other people's minds is at the very heart of the autistic symptomatology: by preventing access to the full range of mental states and efficient mind reading, a deficit in ToM would lead to abnormalities in social development, in communication development, in empathy, and in imitation, all of which require taking other people's perspective.

The ToM deficit hypothesis of autism was put forward after Baron-Cohen, Leslie, and Frith demonstrated that children with autism had massive problems dealing with the Sally-Anne task (Baron-Cohen et al. 1985). In this seminal study, a large majority of typically developing children and of children with moderate learning difficulties passed the test while most children with autism did not. Numerous studies later replicated those findings, bringing further support to the idea that the social and communicative difficulties found in ASDs are rooted in a primary ToM deficit (Baron-Cohen 1995, 2000).

However, it must be noted that there is a subset of children with autism who do pass the Sally-Anne test, which could jeopardize the assumption that the ToM deficit is universal. This criticism led to more research using more sophisticated ToM paradigms, such as second-order false belief tasks. In these tasks, the participant has to represent what someone thinks of what another person thinks. For instance, in the ice cream van task, two characters (John and Mary) are independently informed about the unexpected change of location of an ice cream van. John thus knows that the van has moved, and so does Mary; however, both wrongly *believe* that the other doesn't *know* about this unexpected change in location. Children's understanding of this second-order belief structure is tested by asking them "Where does John think Mary will go for the ice cream?"

Using this paradigm with children with autism, Baron-Cohen (1989) found that 90% of TD children and 60% of children with Down syndrome passed the test. In sharp contrast, none of the children with autism succeeded. This led to the conclusion that although some individuals demonstrate that they can use first-order ToM, they remain unable to handle a two-order false belief task, thereby indicating that they do not have a fully representational ToM. But these results were later criticized because a significant proportion of young adults with a high-functioning ASD appear to succeed even in second-order ToM tests.

Criticisms to these original findings led to the development of two – mutually compatible – hypotheses. The first one is that individuals with

autism who do pass first- and second-order tests come to do so with a significant delay. This fits well with results found in Happé's (1995) meta-analysis of 13 false belief studies showing that the minimum verbal mental age (VMA) at which participants pass false belief tasks is 3.62 years in TD children and 5.5 years in children with ASD. Under the assumption that there is a critical period for the development of numerous cognitive skills, this delay could account for persisting deficits in the communicative and social realms.

The second hypothesis is that surface-level performance is to be distinguished from actual competence. It is indeed possible that the individuals with an ASD who pass ToM tests use strategies that greatly differ from ordinary ToM mechanisms. One should thus refrain from assuming that intact performance reflects intact competence. This is in line with the fact that more advanced tests of ToM reveal impaired performance even in individuals on the highest end of the spectrum. In the Strange Stories test (Happé 1994), for instance, participants are asked to justify why a character might have chosen to say what he says in a complex mentalistic situation. For example, a prisoner gets captured by enemy troops and upon being asked where the rest of his camp is hidden, the prisoner decides to reveal the exact location in the hope that the enemy will believe that he's lying and therefore send troops to the opposite location. Understanding this use of "double bluff" is a complex mind reading achievement that turns out to be especially challenging for individuals with autism, including for those individuals who do pass second-order theory of mind tests. Similarly, Baron-Cohen and colleagues found that adults with a high-functioning ASD who were able to pass first- and second-order standard ToM tests were nonetheless impaired in a subtle form of tests, assessing the ability to "read the mind in the eyes." In this test, participants look at pictures of the eye region displaying specific emotions and select the appropriate emotional adjective best describing the person's mental state (e.g., despondent, relieved, excited, shy). The fact that adults on the highest end of the autism spectrum are less proficient than control populations

in these kinds of tests suggests that difficulties dealing with psychological states are long lasting and can persist in even milder forms of the condition.

Future Directions

Standard false belief tasks and more subtle tests of mind reading have lent support to the idea that ToM deficits are widespread in ASDs. Whether this impairment is primary or simply consecutive to more basic deficits, however, is still debated. In particular, some researchers have argued that ToM deficits may be the consequence of a more primary deficit in social orienting or social attention. More specifically, this alternative hypothesis posits that autism is characterized by a primary disturbance in the motivational and executive processes that prioritize orienting to social stimuli. In this framework, decreased expertise in social cognition and ToM would be the result of reduced time spent attending to the social world (see e.g., Dawson et al. 2002; Schultz 2005). In one case then, impaired ToM is the result of impaired social attention. In the other, impaired ToM is the primary deficit behind decreased social attention. Telling these two hypotheses apart is the matter of further empirical investigation, perhaps through comparison of different clinical groups or longitudinal studies of individual differences within the autism spectrum.

Thimerosal

Paul A. Offit

Division of Infectious Diseases, Department of Pediatrics, The Children’s Hospital of Philadelphia, Philadelphia, PA, USA

Definition

In 1999, the Public Health Service and the American Academy of Pediatrics issued a letter to pharmaceutical companies to remove thimerosal, an ethylmercury-containing preservative, from vaccines as quickly as possible. During the previous decade, as more vaccines were added to the infant vaccination schedule, some of which contained thimerosal, infants were exposed to greater quantities of ethylmercury. By 1999, it was possible for infants to receive as much as 187.5 ug of ethylmercury in the first 6 months of life. Regulators were worried that this quantity of mercury might cause subtle signs of mercury toxicity. Because no studies existed to refute this concern, public health officials cited the precautionary principle and urged removal.

The precipitous and frightening manner in which thimerosal was removed from vaccines in the late 1990s gave birth to several parent advocacy groups, specifically, *Generation Rescue*, *Moms Against Mercury*, and *Safe Minds*. All of these groups believed that mercury had been removed from vaccines because the public health community believed not that it *might* cause harm, but rather that it *had* caused harm. These groups were particularly concerned that thimerosal in vaccines had caused autism.

Although parents’ concern that mercury in vaccines could cause autism was understandable – especially given the manner in which it was removed – several toxicological and biological facts should have been reassuring. First, signs and symptoms of mercury poisoning are clearly distinct from those of autism. Second, ethylmercury is excreted from the body far more quickly than environmental mercury

(methylmercury). Third, the quantities of mercury contained in breast milk and infant formula likely to be ingested in the first 6 months of life were greater than the quantity of mercury contained in vaccines.

Epidemiological studies determining whether thimerosal in vaccines caused autism took advantage of several natural experiments. Western European nations had removed thimerosal from all vaccines by 1991. Also, some Canadian provinces used thimerosal-containing vaccines, whereas others used vaccines containing lesser quantities of thimerosal or no thimerosal. Investigators working in Europe, Canada, and the United States showed that children who received thimerosal-containing vaccines were not more likely to develop autism spectrum disorder or even subtle signs of mercury poisoning than children who had received thimerosal-free vaccines or vaccines containing lesser quantities of thimerosal. Scientists and public health officials are now comfortable that existing studies have refuted the concern that thimerosal in vaccines caused autism.

Definition

Thioridazine is a prescription drug in the group of piperidine phenothiazines in the family of first-generation antipsychotics which has the chemical formula $C_{21}H_{26}N_2S_2 \cdot HCl$. This drug was initially FDA-approved for medical use in the year 1962. This compound has relatively low potency compared to the other first-generation antipsychotics, and its mechanism of action is thought to involve anticholinergic binding. This drug is FDA-approved for the treatment of schizophrenia and can be used to treat aggression and positive symptoms. Observed side effects include drowsiness/sedation, orthostatic hypotension, tachycardia, electrocardiogram (ECG) abnormalities, cardiac arrhythmias, anticholinergic effects, sexual dysfunction, galactorrhea, weight gain, photosensitivity, rashes, and pigmentary retinopathy. Thioridazine has significant potential adverse drug-drug interactions when coadministered with fluvoxamine, fluoxetine, paroxetine, sertraline, pindolol, propranolol, cisapride, fluoroquinolone antibiotics, many other antipsychotics, and tricyclic antidepressants among other drugs.

Definition

Thiothixene is a prescription drug in the group of thioxanthenes in the family of first-generation antipsychotics which has the chemical formula $C_{23}H_{29}N_3O_2S_2$. This drug was initially FDA-approved for medical use in the year 1967. This drug is FDA-approved for the treatment of schizophrenia and can be used to treat borderline personality disorder and schizotypal personality disorder. Observed side effects include drowsiness/sedation, insomnia/agitation, Parkinsonism, akathisia, and weight gain.

Tics

Lawrence David Scahill
 Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA
 Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA
 Department of Pediatrics, Emory University, Atlanta, GA, USA

Definition

Tics are the defining feature of Tourette syndrome. Tics are typically rapid, jerky movements

that may also involve vocalizations. Common tics include eye blinking, facial movements, head jerking, shoulder jerking, and abdominal tensing. Common vocal tics include throat clearing, grunting, coughing, hooting, and making various animal noises. Although tics are the defining feature of Tourette syndrome, tics may also occur in other conditions. Tic-like behaviors do occur in children with autism spectrum disorders.

ASD Autism spectrum disorder

Definition

The term *time experience* has been used in philosophy and descriptive psychopathology to delineate both the explicit and implicit inner experience of time. Explicit time experience (or “macro layer”) entails those aspects of time which we are consciously aware of – or may become aware of – such as the different dimensions of time encompassing past, present, and future or feelings such as boredom and time pressure (Vogel et al. 2018a). Implicit time experience (or “micro layer”) describes the unconscious prerequisites for perception, thinking, and behavior, usually with a focus on the continuity and future directionality of our subjective experience. Importantly, time experience as the experience of time passing by only marginally relates to our time perception (e.g., the ability to explicitly judge time intervals according to the clock or to generate time intervals via button press etc.) (Wearden 2015; Vogel et al. 2018a). With respect to psychopathology in general, time experience provides a holistic understanding of an individual syndrome in terms of a person’s inner experience (Stanghellini 2009, 2010). It has been speculated that the time experience of individuals with ASD differs from those without ASD (Zukauskas et al.

2009; Hohwy et al. 2016; Vogel et al. 2018a, 2019a). The respective proposals state that the processes underlying implicit time experience take more time in individuals with ASD, due to a more detailed perception of their environment. This might affect the intrapersonal coordination of information processing and might cause inter-subjective asynchronies potentially impeding both perceptual processing and complex behavior (Bloch et al. 2019). Persons with ASD may consequently experience continuous interruptions of their time caused by their environment. As a result, rituals and structured repetitive behavior are used to increase predictability, decrease future anxiety, and avoid interruption.

Historical Background

Research on time experience has a long-standing tradition in philosophy and psychiatry. Its roots go back to the philosophical discipline of phenomenology (Kupke 2009). Among the most prominent theories are the works of Edmund Husserl, Henri Bergson, and Martin Heidegger (Bergson 2001; Heidegger 2008; Husserl 2012). Their ideas were adopted by psychiatrists including Erwin Straus, Ludwig Binswanger, Eugene Minkowski, and Viktor Emil von Gebsattel. This early interdisciplinary approach has since inspired many other psychiatrists, psychologists, and philosophers alike. The subsequent research has largely focused on the phenomenological description of mental disorders, such as major depression (von Gebsattel 1928, 1954; Straus 1928; Lewis 1932; Binswanger 1960; Minkowski 1933; Fuchs 2001, 2013; Kupke 2005; Wyllie 2005; Ratcliffe 2012; Stanghellini et al. 2017; Vogel et al. 2018b), mania (Minkowski 1923; Binswanger 1960; Moskalewicz and Schwartz 2018; Martin et al. 2019), and schizophrenia (Bouman and Grünbaum 1929; Lewis 1932; Minkowski 1933; Vogeley and Kupke 2006; Fuchs 2007a; Kupke 2009; Stanghellini et al. 2015; Moskalewicz 2018; Vogel et al. 2019b). Some studies were

also dedicated to obsessive-compulsive disorder (von Gebsattel 1928, 1954), addictive behavior (von Gebsattel 1954; Moskalewicz 2016b), eating disorders, or personality disorders (Fuchs 2007b; Stanghellini and Mancini 2019). So far only very few studies have focused primarily on ASD (Zukauskas et al. 2009; Hohwy et al. 2016; Vogel et al. 2019b). However, an extensive and increasing body of research on time perception (e.g., the ability to explicitly judge time intervals according to the clock or to generate time intervals via button press etc.) has yielded interesting results for ASD and in turn inspired research on time experience (for review see Allman and Meck 2011; Falter and Noreika 2014; Allman and Falter 2015; Casassus et al. 2019).

Current Knowledge

“Lived Time”

The concept underlying time experience as a whole is commonly referred to as “lived time” (Straus 1928; von Gebsattel 1928; Fuchs 2001, 2013; Broome 2005; Kupke 2005; Wyllie 2005; Gallagher 2012; Moskalewicz 2016a; Stanghellini et al. 2015). In simple terms, it supposes that human consciousness is not only dependent on time as a prerequisite to our basic existence but that it is the direction of time which provides goals and meaning: actions were prepared in the immediate or far away past and are being performed in the present in order to influence the near to distant future (Vogel et al. 2018a).

Time experience may be differentiated into an explicit, controlled, and conscious aspect and an implicit, automatic, and unconscious aspect. Importantly, this division is conceptual; it is much harder to draw clear and distinctive lines between the two concepts in the empirical domain (Vogel et al. 2018a). However, from a scholarly perspective, the division into such an implicit and an explicit time experience enables an orderly scientific approach to the otherwise elusive research topic of human time.

Time is not static, but dynamic. According to the theory of lived time, the essential constituent of its dynamicity is the directionality toward the

future. This dynamic character has consequences for the experience of the present that may vary in its temporal extension depending on its relationship to the future (as determined by the past). For example, depending on a current situation and its demands, the “present” could refer to an hour, a particular day, or a life phase – or even all three. We live our time from the past in the present into the future (Kupke 2009; Vogel et al. 2018a). In emphasis of its future directionality, lived time has also been called the “becoming” (“Werden”) (von Gebsattel 1954; Straus 1947; Minkowski 1933; Fuchs 2013; Vogel et al. 2018a, b) or “striving” (“Streben”) (Minkowski 1923, p. 220; Minkowski 1933).

Explicit Time Experience

Explicit time experience (or “macro layer of time”) (for terminology see Fuchs 2005; Vogel et al. 2018a) entails the three dimensions of the structure of time: past, present, and future. Along these dimensions, we construct our individual autobiographical narratives and identities (Carr 1986; Stanghellini and Mancini 2017, p. 56 ff). Humans seemingly effortlessly locate themselves, their respective present, and their memories of the past on a virtual time line. Also, they devise plans and prospects for the future on that time line. For each individual these biographic events are inter-related and thereby provide each other with meaning and significance (Stanghellini 2017; Stanghellini and Mancini 2017, p. 57 ff). As long as the execution of the present aligns with our ideas about our past and future, we normally do not pay attention to time: explicit time blends with implicit time (Fuchs 2005; Vogel et al. 2018a). However, if our present activity in some way does not fit our narrative or is out of tune with our plans, we increasingly become aware of time (Vogel et al. 2018a).

The dynamic character can be illustrated by extreme cases of time pressure and boredom. Under time pressure, the available time is experienced as not sufficient to perform a particular action to reach a particular goal. As a consequence, the present appears to be passing too quickly to attain the said goal. If, however, we are bored, the present does not seem sufficiently

(full)filled. It may seem meaningless or empty in light of our plans and wishes. In terms of lived time, this can be understood as an inability to pursue a preferred activity or goal, and it explains why someone bored would prefer a different (more satisfying) activity (Fuchs 2005; Elpidorou 2018). This tension between present and future directionality causes time to be experienced as passing more slowly. Contrarily to both time pressure and boredom, we experience the so-called flow state when being completely immersed in lived time. During flow, external requirements and own abilities are optimally balanced (Csikszentmihályi 1990).

The explicit experience of time has been suggested as altered in a variety of psychiatric conditions (Straus 1928; von Gebattel 1928; Lewis 1932; Fuchs 2001, 2013; Broome 2005; Kupke 2005; Wyllie 2005; Gallagher 2012; Moskalewicz 2016a; Stanghellini et al. 2015; Vogel et al. 2018a). For example, its disturbances are a frequently reported symptom of depressive disorders. It has repeatedly been proposed that in major depression the future directionality of time experience loses extension, and the personal future appears closed off. Depressed patients lose their inherent ability to influence the future in the present. The present is rendered meaningless, the past unchangeably shameful, and the passage of time turns into a dragging and repetitious continuance of suffering. The emerging syndrome of disturbed time experience in the case of depression has been referred to as “blocked future” (von Gebattel 1928; Straus 1928; Fuchs 2001; Wyllie 2005; Stanghellini et al. 2017), “disturbance of (vital) becoming” (Straus 1928; von Gebattel 1954; Minkowski 1933; Fuchs 2013), “disturbance of protention” (Binswanger 1960), or “disorder/disturbance of conation” (Stanghellini et al. 2017) (for review see Vogel et al. 2018a, b).

With regard to time experience, ASD stands out among psychiatric diagnoses as the conceptualization of ASD in the International Classification of Diseases (ICD) (World Health Organization. 1992), and the Diagnostic and Statistical Manual of Mental Disorders (DSM) (American Psychiatric Association 2013)

contains a distinctly temporal symptom: “restricted, repetitive patterns of behavior, interests, or activities” (American Psychiatric Association 2013, p. 50). Temporal structure, repetitive routine, difficulty or inability to spontaneity, and insistence on sameness have recently been described in terms of time experience as part of an overarching syndrome. In a qualitative study consulting adults with high-functioning ASD about inner time experience, Vogel et al. (2019a) were able to describe symptom formation in terms of time experience. Building on earlier qualitative research (Zukauskas et al. 2009; Vogel et al. 2018a), the results indicate that routine was described as bringing about a pleasant fading out of the felt passage of time as an uninhibited immersion into lived time. Non-surprisingly, disruptions of routine were experienced as unpleasant. Due to a felt unpredictability, individuals with ASD reported a particular fear and anxiety concerning the very close to near future. This fear seemed to inspire excessive planning and structuring of the future through further routine. As long as the plan succeeded, time experience followed the same rules in persons with and without ASD.

However, plans can be neither flawless nor rigidly adhered to in everyday life without a certain ability to take into account unpredictability and surprise. Hence, the pleasant continuation of routine is usually interrupted at some point – especially when it comes to particularly unpredictable and complex situations such as social interactions. These interruptions are an external cause of a fragmentation of time experience. This discontinuation of the time line relates to the experience of past and future events that are seemingly factual and isolated from the present (Zukauskas et al. 2009; Vogel et al. 2019a). Prospectively overcoming and retrospectively making sense of these separate temporal entities seems to necessitate a considerable degree of effort. Hence it has been argued that the degree of cognitive functioning and overall resources attributable to planning and integrating of temporal structure determines symptom severity and potentially also depressive comorbidity in ASD (Boucher 2001; Fein et al. 2013).

Implicit Time Experience

Implicit time experience (or “micro layer of time”) (for terminology see Fuchs 2005; Vogel et al. 2018a) refers to the unconscious basis of experience. Its most important foundations are continuity and the future directionality of this subpersonal, unconscious basis of consciousness/experience (Dainton 2006; Fuchs 2013; Wiese 2017). It is this fundamental continuity and directionality that makes possible the similar principles in explicit time experience (Vogel et al. 2018a). The same principles have recently found their way into neuroscientific concepts as the putative basic requirements of consciousness in the brain (Hohwy et al. 2016; Wiese 2017; Vogel et al. 2018a). A variety of psychological and neurophysiological processes have been proposed as underlying the supposed alterations in time perception and experience in ASD (e.g., genetic variances (Wimpory et al. 2002; Nicholas, B. et al. 2007) or hormonal dysregulation (Tordjman et al. 2015)). Concerning the theory of interrupted time experience, examining its underlying implicit mechanisms requires the examination of the unconscious processes constituting the flow or stream of consciousness (Vogel et al. 2018a). As a starting point of inquiry, it has recently been suggested that predictive processing or Bayesian perceptual inference constitutes the passage of time (Hohwy et al. 2016; also see Vogel et al. 2018a). The major advantage of this line of reasoning is that it elegantly combines both phenomenological ideas grounded largely in the Husserlian analysis of time consciousness and trending neuroscientific theories (Hohwy et al. 2016; Wiese 2017).

Predictive processing in the brain assumes that the brain calculates its output (i.e., perceptions and experience) through the combination of preconceived top-down inferences and bottom-up perceptual information (e.g., Friston et al. 2014). Put simply, at any point in time, the brain creates a hypothesis of what its next perceptual input will most likely be. This prediction is based on the previous input, i.e., earlier experience and directly preceding percepts. This hypothesis is called a prior. The prior is compared to the actual perception. As long as

perceptual input and prior match, the prior remains active and the output remains unchanged. If incoming information and prior do not match, a prediction error is calculated. In case of a prediction error, the neural system passes the error along a hierarchical organization of alternative potential priors in order to explain the error (i.e., unexpected or unusual percept). This hierarchy ranges from lower priors reflecting simple, specific assumptions on the causes and contents of perception to higher priors reflecting general beliefs. The more “unexpected” a new perceptual input, the higher the resulting prediction error will be, and the further it potentially will have to travel up the hierarchy until it has been explained away and resolved. The result from this calculation is called the posterior. The active prior is subsequently replaced by the posterior which thereby becomes the next percept’s better fitting prior. The transition from prior to new prior has been postulated to produce the experience of temporal flow (Hohwy et al. 2016).

Theorists on Bayesian processing in the brain have proposed so-called hypo-priors for ASD (Pellicano and Burr 2012; Hohwy et al. 2016), i.e., priors which prioritize more perceptual input and hence provide more perceptual detail. A brain with higher-detailed priors would need more time to process and extract relevant information, comparatively slowing down processing speed and the internal flow of information (Hohwy et al. 2016). If the resultant speed of prior changes drops below the speed of changes in the external world, the external changes might appear as happening too fast (Gepner and Féron 2009; Hohwy et al. 2016). In other words, due to a more detailed perception, individuals with ASD may not be able to process information fast enough to keep up with their surroundings. The need to process new, fast incoming and especially unexpected, spontaneous information effectively interrupts the currently ongoing processing of information. Although the prior updating process does not directly reflect experienced speed of time, the divergence of internal and external temporal flow may become aware in changes in the explicit velocity of time (Fuchs 2005; Vogel et al. 2018a).

Interrupted Time Experience

Complementarily to these qualitative descriptions and hypotheses, observations from experimental psychology can also be read as indications of an interrupted time experience in ASD. Wimpory et al. (2002) proposed a “Social Timing Hypothesis of Autism.” According to the hypothesis, persons with ASD cannot sufficiently synchronize with others on a behavioral level, due to suspected anomalies in clock genes (Nicholas et al. 2007). Boucher et al. (2007) studied children with ASD and found impairment in diachronic thinking. Diachronic thought (Montangero 1992) entails the ability to imagine past or future stages of a present situation, object permanence, and the ability to infer a process from successive events and vice versa. In other words, children with ASD may have a differing concept of temporal continuity or a delayed development thereof. Concerning the passage of time and events, an environment changing too fast due to aberrant connectivity and neuronal synchronization has been discussed as constituting ASD (Gepner and Féron 2009). Atypicalities in intrapersonal synchrony have been speculated to cause interpersonal asynchronies in ASD (Bloch et al. 2019). Although it still remains unclear, whether these and other variations in ASD are due to distinct impairments in time perception, they have been suggested to produce difficulties in interpersonal and communicative coordination (for review see Allman and Meck 2011; Falter and Noreika 2014; Allman and Falter 2015; Casassus et al. 2019). In accordance with interrupted time experience, stereotyped behavior may serve as a compensatory mechanism for these deficits (Allman et al. 2011).

The integrated analysis of time and temporality in ASD understands patients’ symptoms and individual syndromes as a meaningful whole (Stanghellini 2009, 2010) which emerges from a distinct experience of time. Repeat interruptions by an environment that is too fast or too unpredictable cause subjective difficulties depending on the availability of cognitive resources. Due to their innate complexity and relatively high spontaneity, we may assume that communicative situations are especially difficult.

Symptoms such as repetitions, routine, insistence on sameness, and intensified focus (American Psychiatric Association 2013, p.50) can be interpreted as compensatory mechanisms to reestablish or guarantee undisturbed time experience.

Future Directions

Interrupted time experience in ASD remains a hypothesis primarily derived from qualitative exploration. As with other findings on time and ASD, the reliability and specificity of the theory remain uncertain (see Falter and Noreika 2014 for discussion; and Casassus et al. 2019 for review). However, it holds tremendous potential for further investigation of time experience in ASD. In its explorative and observational character and the need to contextualize and understand the inner lived experience of persons with ASD, interrupted time experience can become informative for research on the putative underpinnings of human perception and experience in ASD, and beyond.

A potential neural target for research on time experience both generally and in ASD is the so-called default mode of the brain. The default mode (or resting state) is the brain’s activity measurable while the brain is not engaged in any specific task (Raichle et al. 2001; Northoff 2016a). Changes in the temporospatial activity of the default mode have recently been put forward as being related to psychopathological phenomena of time experience (Northoff 2016a, b; Northoff and Stanghellini 2016). Should the concept prove true, alterations in the brain’s resting state as repeatedly described in ASD (e.g., Weng et al. 2010; Anderson et al. 2011; Joshi et al. 2017) could be used to explain altered time experience.

Future research should further attempt an operationalization of interrupted time experience as a descriptive syndrome. Further conceptualization and the inclusion into a standardized diagnostic protocol allows for testing of the experiential hypothesis. If such a descriptive approach succeeds in clinical practice, it would inform and specify diagnostic procedure, foster our

Time Experience in Autism Spectrum Disorder, Table 1 Descriptive view of the syndrome of interrupted time experience in ASD. (Amended acc. to Vogel et al. 2019a)

Experience	Definition	Suggestions for related questions
The faded out passage of time	The passage of time is hardly or vaguely felt. A bad sense of time. Fading is usually amplified by structured and routine activity	“Do you have a good or a bad sense of time?”; “How do you keep track of time?”; “What makes you forget about time?”
The present as confined activity	The present consists of one distinct activity, usually deemed important, necessary, or meaningful. Routine is experienced as beneficial. Interruptions are experienced as distressing	“What does ‘the present’ mean to you?”; “How does routine/repetition influence your experience of the present?”; “Is the present a point in time, or is it extended?”
The past as isolated memories	The past is described as a repetition of facts. Although meaningful and influential, the past is not necessarily part of the lived present	“What do your past experiences (<i>or a specific memory</i>) mean to you?”; “Do your past experiences influence your decisions? If yes, how?”
The planned future	The future is experienced as uncertain and frightening. The future is rigorously planned to avoid unexpected interruption	“What does the future mean to you?”; “Are you afraid of the future/the unexpected?”; “Do you distinguish between a near and a far-away future?” “Do you feel that it is possible to plan for the future?”; “Do you spend much time/effort on planning? Describe to me, how you would plan your day?”; “Why do you make plans?”

understanding of persons with ASD, and help identify, therapeutically employ, and improve strengths and resources.

Vogel et al. (2019a) have provided a table (Table 1) describing a potential syndromic description of interrupted time experience. We have amended the table with explorative questions designed to approach, identify, and potentially understand the time experience of a patient with suspected ASD in a diagnostic interview. Of course these questions are preliminary, are difficult to understand, have never been used systematically, and will need further study before being able to be more widely used in clinical practice. Additionally quantifying psychometric scales need to be developed both to facilitate standardized clinical application and a broader use in scientific research.

Time Interval

► [Latency, Second Edition](#)

Time Management

Mark Groskreutz

Special Education and Reading Department, The Center of Excellence on Autism Spectrum Disorders, Southern Connecticut State University, New Haven, CT, USA

Definition

Time management is the process through which a person plans for, initiates, and completes one or more activities consistent with a predetermined sequence and/or schedule. Time management is important for many everyday activities, such as getting ready for school or work, completing responsibilities on time, arranging priorities, etc. For individuals with autism spectrum disorders (ASDs), the time management process can be very challenging to complete independently. Some individuals with ASDs may need explicit teaching with initial or ongoing support to manage their time effectively.

To help address time management issues, researchers and practitioners have used a variety of supports. Visual supports may be used to help arrange several activities into a logical order. Once arranged, visual supports then show a particular sequence to be followed (e.g., activity schedules; McClannahan and Krantz 2010). While visual support can be used to help a person with an ASD complete a routine without assistance from another person, this does not mean he or she is independently completing the entire time management process.

Learning to manage one's time requires consideration of a wide variety of variables, such as relevant activities, time frames, and resources. Interventions designed to improve time management may need to address each of these areas if the person is to learn to manage their time independently. For individuals who have not yet mastered time management, visual supports, such as activity schedules, may be particularly effective in increasing independent completion of even

complex routines with little or no intervention from care givers during the activities.

Time Trends in Diagnosis

Catherine E. Rice

National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, GA, USA

Definition

Autism is one of several pervasive developmental disorders (PDDs) characterized by atypical development in socialization, communication, and behavior. Symptoms of autism and related conditions are typically present before age 3 years and often are accompanied by unusual patterns in cognitive functioning, learning, attention, and sensory processing. In the past decade, the conditions of autistic disorder, Asperger's disorder, and pervasive developmental disorder – not otherwise specified – have been referred to as the “autism spectrum disorders” (ASDs). ASDs are defined by a pattern of development which emerges in the first few years of life, and there is currently no biologic test to confirm the diagnosis. Therefore, these developmental disabilities are typically diagnosed by professionals who have an advanced degree and training in the evaluation of developmental status, such as physicians and psychologists. Determining that a child's

developmental profile is consistent with one of the ASDs requires consideration of the way the child communicates, interacts, behaves, learns, and plays and is guided by diagnostic criteria. Since autism was first described about 70 years ago, these criteria have changed.

Historical Background

Autism was first described in 1943 by psychiatrist Leo Kanner working at Johns Hopkins University (Kanner 1943). Dr. Kanner described 11 children referred to him because of unusual development. He noted common patterns among the children's behavior including "extreme autism, obsessiveness, stereotypy, and echolalia." He also noted similarities to children with schizophrenia but offered that autism was unique in the "extreme aloneness" and lack of social contact with "intelligent relation to objects" from very early in life. Also in the 1940s, Dr. Hans Asperger of Austria was also describing a group of children he saw clinically who had significant social impairments but more typical language content than the children described by Kanner. They were not aware of each other's work, but both used the term "autism" to describe a unique group of children. Although there are reports of socially isolated individuals with unusual behaviors throughout history, these efforts were the first to describe the developmental pattern as a specific psychiatric condition (Rutter and Schopler 1987).

Kanner's description (1943; Eisenberg and Kanner 1956) of autism provided the dominant guidance for describing the features of autism until the 1970s. Although Kanner noted that autism had a unique profile different from schizophrenia, autism was classified as a form of early-onset schizophrenia (Creak et al. 1964) in the American Psychiatric Association's Diagnostic and Statistical Manual (DSM) (American Psychiatric Association [APA] 1952, 1968) (see Fig. 1 summarizing autism diagnostic criteria). The DSM is the standard for clinical diagnosis of psychiatric disorders which impacts the way in which professionals identify and label these

Time Trends in Diagnosis, Fig. 1 Summary of Autism/ASD prevalence by year and diagnostic criteria

conditions. The DSM is periodically revised. During the 1970s, there was a shift to distinguish autism from childhood schizophrenia with the recognition that the latter usually involves a period of typical functioning with the later emergence of unusual thoughts and behaviors and a loss of contact with reality. Criteria for autism by Rutter (1978) and Ritvo and Freeman (1978) emphasized the early onset of autism in the first three years of life and the differences and overlap between autism and mental retardation. Around the same time, Lorna Wing translated Asperger's earlier descriptions of more verbal children with autism into English. She also described social, communication, and behavioral features as the core of autism but noted that there is a continuum of social functioning indicated by three groups: "aloof," "passive," and "active but odd" (Wing and Gould 1979).

The *DSM-III* (APA 1980) distinguished autism as one of the "pervasive developmental disorders" and severed the connection to schizophrenia. Autism was now classified as one of several related developmental disorders where the typical social and language skills and behaviors do not occur as expected from very early in life. The next edition, *DSM III-R* (APA 1987), revised the specific criteria which make up the social,

communication, and behavioral symptoms of autism and the lowest threshold diagnosis of PDD-NOS. More significant changes were made with the DSM-IV (APA 1994) and the subsequent text revision (APA 2000) which mirrored the broadening of conditions included as a PDD for the International Classification of Diseases, tenth edition (ICD-10) (WHO 1992). Starting in the early 1990s, Asperger's disorder was included for the first time as a PDD. Since the publication of the *ICD-10* and *DSM IV* and *IVTR* criteria for the PDDs in the early 1990s, a great deal has changed in the identification and conceptualization of autism and related disorders. As noted earlier, three of the conditions are now referred to as the ASDs to reflect the "spectrum" of deficits and skills across multiple domains which share core social, communication, and behavioral features present during the first 3 years of life. However, within this spectrum, individual features and functioning across domains may vary from mildly to severely affected. In addition, there is a recognition that ASDs can co-occur across the whole range of intellectual functioning and with other developmental and medical conditions.

Current Knowledge

In the past 20 years, there have been increases in the numbers of people identified with an ASD compared to the past. This has sparked debate about how much of the increases in the prevalence of ASDs are explained either by changes in identification patterns and, therefore, an artifact of changing diagnostic criteria and awareness or by a true increase in symptoms among children born in more recent times. One issue to examine is whether the changing diagnostic criteria for the ASDs have influenced estimates of the prevalence of ASDs over time. The first epidemiologic studies of autism prevalence in the population were done by Lotter in the UK (1966, 1967) and were based on Kanner's criteria. Since that time, many studies based on each of the major diagnostic criteria have estimated the prevalence of ASDs (see graph). From the 1940s until the

1980s, autism primarily referred to more severely affected individuals with autistic disorder and was thought to be rare, affecting approximately one in every 2,000 (0.05%) children (Fombonne 2009; Rutter 2005). Several studies using *ICD-10* and *DSM-IV* have been done in industrialized countries identifying not only autism but the wider spectrum with surprising consistency indicating a best estimate of combined ASD prevalence at 6 or 7 of every 1,000 (0.6–0.7%) children with ASDs (CDC 2007; Fombonne 2009). These estimates are more than 10 times higher than estimates using earlier criteria. However, some of the most recent population-based studies have documented even higher ASD prevalence estimates of >1% (Baird et al. 2006; Baron-Cohen et al. 2009; CDC 2009; Honda et al. 2005; Kadesjo et al. 1999; Kogan et al. 2009) and even as high as 2.6% (Kim et al. 2011; Roelfsema et al. 2012) among children in areas of Asia, Europe, and North America. Can the difference of 1 in 2,000 children to about 1 in 100 be accounted for by the shift from seeing autism as a severe, rare disorder to the broader spectrum? One effort to retrospectively apply more modern criteria to an older study estimated a prevalence of about 4 per 1,000 children, indicating that older studies underestimated prevalence as they considered a more strict interpretation of autism (Heussler et al. 2001). Although earlier studies likely underestimated ASD prevalence by today's standards, there are many other factors to take into account when sorting out time trends in ASD identification. For example, the age of onset required for diagnosis has changed over time and can influence ASD prevalence estimates. In addition, there are multiple identification and risk factors which could also influence the identification and/or development of an ASD.

Few studies have tracked the same population over time to evaluate ASD prevalence changes. The Autism and Developmental Disabilities Monitoring (ADDM) Network [established by the Centers for Disease Control and Prevention (CDC) in 2007 to characterize and track the prevalence of ASDs among children in multiple areas of the United States] reported an overall 57%

increase in identified ASD prevalence among 8-year-old children over a 4-year period from 2002 to 2006 (Centers for Disease Control and Prevention [CDC] 2009). On average, ASD prevalence increased across all sex, racial/ethnic, and cognitive functioning subgroups. Although some of the changes in ASD prevalence could be attributed to improved identification in the areas studied, particularly of some subgroups such as Hispanic children and children without intellectual disabilities, these patterns were not consistent among sites and cannot completely explain a greater than 50% prevalence increase in such a short time period. These findings, in addition to trends across multiple single studies, raise questions about what other identification and potential risk factors in addition to changes in diagnostic criteria are influencing increasing prevalence estimates of ASDs. At this point, it is clear that shifts in the diagnostic criteria for ASDs have had an impact on the identified prevalence, but no single factor explains the changes identified in ASD prevalence over time, and much needs to be done to understand the relative contribution of the multiple factors involved.

Kanner Criteria (1943)

- Inability to relate to people; language does not convey meaning; food refusal; fear of noises; limited but good relations with objects; present from the beginning of life

Eisenberg and Kanner (1956)

- Extreme self-isolation (lack of affective contact) and extreme repetitive and ritualistic behavior (perseveration of sameness) DSM-I (1952) and DSM-II (1968)
- Part of schizophrenia, childhood type manifested by autistic, atypical, and withdrawn behavior; unevenness, immaturity, or inadequacy of development

Creak et al. (1964)

- Schizophrenic syndrome in childhood including gross and sustained impairment of

emotional relationships with people, lack of self-awareness, preoccupation with objects, resistance to change, abnormal perceptual and sensory issues, excessive anxiety, delayed language, unusual activity levels, unusual intellectual skills

Rutter Criteria (1978)

- Emphasized social and language development delayed and unusual for the child's intellectual ability; insistence on sameness, abnormal pre-occupations, or resistance to change; onset before 30 months

DSM-III (1980)

- Differentiated autism from schizophrenia (not a psychiatric disorder, but developmental)
- Concept of "PDD" introduced: infantile autism; childhood-onset PDD; atypical PDD
- Autism: Pervasive lack of responsiveness to other people (autism); gross deficits in language development or peculiar speech patterns; bizarre responses to the environment; onset before 30 months
- Childhood-onset PDD: gross and sustained impairment in social relationships with at least three of the following: excessive anxiety, inappropriate affect, resistance to change, movement oddities, abnormalities of speech, sensory issues, self-injury; onset between 30 months and 12 years

DSM-III-R (1987)

- Concept of PDD continued: autism and PDD-NOS
- *Autism: has eight criteria indicating qualitative impairment in reciprocal social interaction, in verbal and nonverbal communication and in imaginative activity, and in markedly restricted repertoire of activities and interests; onset during infancy or early childhood*
- PDD-NOS: qualitative impairment in the development of reciprocal social interaction and of verbal and nonverbal communication skills; may have a markedly restricted repertoire of activities and interests

DSM-IV (1994) and DSM-IV TR (2000)

- Similar to ICD-10 (1992)
- Expanded PDD concept: autistic disorder; Asperger syndrome; Rett syndrome; CDD; PDD-NOS
- Autism: has six criteria indicating qualitative impairment in social interaction and communication, and restricted, repetitive, and stereotyped patterns of behavior; onset prior to 36 months
- PDD-NOS: Severe and pervasive impairment in the development of reciprocal social interaction or verbal and nonverbal communication skills, or when stereotyped behavior, interests, and activities are present; includes “atypical autism” presentations that do not meet the criteria for autistic disorder because of late age at onset, atypical symptomatology, or sub-threshold symptomatology, or all of these

DSM 5 (estimated 2013)

- Proposes to collapse PDD subtypes into a single category of “autism spectrum disorders”
- Proposed ASD: persistent deficits in social communication and social interaction across contexts not accounted for by general developmental delays; restricted, repetitive patterns of behavior, interests, or activities; present in early childhood; symptoms limit and impair everyday functioning
- <http://www.dsm5.org>

Future Directions

Despite the fact that ASD prevalence estimates based on the DSM-IVTR criteria continue to increase, there will be another revision of the diagnostic criteria for autism and related conditions with the upcoming publication of the fifth edition of the DSM (<http://www.dsm5.org>) anticipated for 2013. The current proposed criteria collapse several of the PDD subtypes into one category of autism spectrum disorders. As it stands now, there is greater focus on distinguishing core social communication and interaction and repetitive behaviors, interests, and activity symptoms of ASDs in the context of language level, cognitive functioning,

and other indicators of functioning. In the clinical and research fields, there is a move away from the categorical identification of autism as being present or not present with the recognition that some of the core domains associated with ASDs are distributed in a more continuous way in the population (Constantino 2011). There is also increasing interest improving the utility of diagnoses to inform everyday supports and services for people with ASDs. This includes incorporating information on developmental changes and better understanding impact of ASD characteristics on daily functioning (Happé 2011; Lord 2011). The significance of the upcoming revised diagnostic criteria for the ASDs remains to be seen, but impact on identified prevalence of ASDs is highly likely (Mattila et al. 2011).

Definition

Time-out is a procedure that involves removing an individual from positive reinforcement. It is typically employed as a punishment technique. Often, it involves removing an individual from a particular setting in which they displayed inappropriate behaviors and placing the individual in a non-reinforcing setting, such as a chair in the corner, their bed/crib, and outside the classroom. Time-out also may include removal of items or materials that are reinforcing. The term “time-out” was first coined by Arthur Staats in the late 1950s as an effective procedure he used with his typically developing children to decrease their disruptive behaviors, such as crying (Staats 1971). Montrose

Wolf and others (e.g., Allen et al. 1964) used the procedure more systematically as a behavior management technique in which individuals are removed from positive reinforcement. While this technique is generally effective with typically developing children, it may serve as a (negative) reinforcer for children with autism, who may find some of the demands of social interaction aversive and time alone rewarding (Solnick et al. 1977). Specifically, social isolation may not be aversive to a child with autism; thus, time-out may be rewarding to the child. Time-out is often used in place of physical punishment but is most effective when used with other procedures, such as extinction, teaching appropriate replacement behaviors, and differential reinforcement of appropriate behaviors.

Heart-hand syndrome; Timothy Syndrome – 1 (TS1); Timothy Syndrome – 2 (TS2)

Short Description or Definition

Timothy syndrome (TiS) is a rare multisystem developmental disorder caused by a single de novo mutation in the $Ca_v1.2$ L-type calcium channel gene *CACNA1C*. TiS is characterized by physical malformations, cardiac defects, and autism. Individuals with TiS exhibit dysmorphic facial features such as rounded faces, flat nasal bridges, baldness, and abnormal dental anatomy. Patients also possess webbing of toes and fingers (syndactyly). Cardiac deficits of TiS include a severe prolongation of the QT interval (electrocardiographic indication of prolonged heartbeat), significant arrhythmia, and congenital heart disease. Developmental delays associated with TiS include language, motor, and cognitive impairments. Language is affected in the domains of articulation, reception, and expression. Cognitive features include impairment in communication, socialization, daily living skills, as well as intellectual disability. Individuals with TiS meet the criteria for autism spectrum disorder.

Categorization

Phenotypic concurrence of cardiac arrhythmia, long QT, and syndactyly (webbing of fingers and toes) are indicative of TiS (Marks et al. 1995);

DNA sequence analysis is used to confirm TiS (Frohler et al. 2014). Depending on the point mutation in either the mutually exclusive exon 8 or exon 8A, TiS diagnoses are categorized into two subtypes: TS1 (G406R in exon 8A) and TS2 (G406R or G402S in exon 8). The exon 8A-containing variant of $Ca_v1.2$ mRNA is primarily expressed during development and at lower levels (~20%) than the dominant exon 8 (Panagiotakos et al. 2019). A glycine to arginine substitution at residue 406 (G406R) in the alternative splicing variant of exon 8A of the *CACNA1C* gene encoding $Ca_v1.2$ calcium channel confirms typical Timothy Syndrome variant 1 (TS1) (Splawski et al. 2004). The atypical Timothy Syndrome variant 2 (TS2), a more severe form of TiS, results from the G406R mutation occurring in the more highly and persistently expressed exon 8 (Panagiotakos et al. 2019). Patients with atypical TiS do not present with syndactyly (Splawski et al. 2005), a particular phenotypic distinction from TS1. Additionally, TS2 can arise from two mutations of $Ca_v1.2$, in exon 8: G406R and G402S. The G406R mutation in atypical TS2 leads to many of the same cardiac and neurological phenotypes as classic TS1, including diagnosable ASD-associated behaviors. Patients with atypical TS2 from a G402S mutation also possess significant cardiac symptoms, including QT interval elongation as well as some neurological symptoms. Though TS2 patients with the G402S mutation possess degrees of intellectual disability and some developmental delay (Diep and Seaver 2015; Hiippala et al. 2015; Splawski et al. 2005), these patients do not present with cognitive deficits associated specifically with Autism Spectrum Disorder (ASD), an important distinction from the G406R variant of TS2 (Hiippala et al. 2015; Splawski et al. 2005). There have also been singular cases of patients presenting with TiS who exhibited mutations in *CACNA1C* gene but not within exon 8/8A (Boczek et al. 2015; Landstrom et al. 2016).

Epidemiology

TiS results from de novo mutations and is extremely rare (Splawski et al. 2004). Inheritance patterns of TiS are sporadic; parents of affected

children typically do not have TiS (Marks et al. 1995; Splawski et al. 2004). However, genetic mosaicism, in which a two or more cell populations in an individual express different genotypes, can lead to inheritance of the mutation in offspring (Gao et al. 2013; Splawski et al. 2004, 2005).

Natural History, Prognostic Factors, and Outcomes

Timothy Syndrome was initially identified in the early 1990s as a novel cardiac arrhythmia that presented with webbing of fingers and toes (syndactyly) and described as a unique form of heart-hand syndrome (HHS). TiS was first identified in Germany by Dr. Reichenbach who recorded a significantly elongated QT-interval and syndactyly in a new born. Long QT-interval and synostoses of the carpus in the father suggested a significant genetic component to this syndrome (Reichenbach et al. 1992). Shortly after, Dr. Mark Keating reported several case studies of infants possessing the same phenotypic association of cardiac arrhythmia and syndactyly. The three children were hypothesized to have the same novel form of long QT-syndrome and were at high risk of sudden death. The patients also possessed other congenital cardiac malformations, but only long QT-interval and syndactyly were consistent across individuals. Dr. Keating and colleagues hypothesized a genetic mechanism for this disease (Marks et al. 1995). The syndrome was named Timothy Syndrome after Katherine Timothy, a nurse at the University of Utah who originally identified this phenotype across different infants. As medical treatment of TiS improved and extended the lives of patients, it became clear that TiS was a major multisystem disorder affecting the heart, skin, eyes, teeth, immune system, and brain (Splawski et al. 2004).

Cardiac abnormalities in TiS are severe and are associated with sudden death (Marks et al. 1995). All children with TiS possess elongated QT intervals and arrhythmias, with 70% of patients experiencing a life-threatening arrhythmic episode. Arrhythmia in TiS can occur as ventricular tachycardia or bradycardia from atrioventricular block (AV block). TiS mutations also result in

hypertrophic cardiomyopathy and ventricular systolic dysfunction (Lo et al. 2005). Patients with TiS also possess congenital heart disease including patent ductus arteriosus (60%), patent foramen ovale (30%), ventricular septal defects (20%), tetralogy of Fallot (6%), and cardiomegaly (35%). Because of the severe cardiac arrhythmia in TiS, many children with TiS die early in infancy and childhood. The average age of death in children with TiS is 2.5–3 years (Splawski et al. 2004).

Children with TiS experience a number of medical difficulties in addition to heart abnormalities. Skin and facial abnormalities are the early phenotypic features of TiS. All children with TiS have syndactyly of the fingers and occasionally toes, as well as baldness at birth. Many children with TiS will have other facial and skin features. Identifiable facial dysmorphism includes rounded faces, flat nasal bridges, thin upper lips, and receding upper jaws. Dentition development of children with TiS is abnormal, characterized by small teeth with soft, poorly formed enamel (Papineau and Wilson 2014; Splawski et al. 2004). Other facial difficulties in TiS patients include nearsightedness (25%) and sinusitis (30%). Children with TiS are likely to present with pulmonary complications such as pneumonia, bronchitis, and pulmonary hypertension, as well as gastrointestinal difficulties. Episodic hypocalcemia and hypoglycemia are present in about 33% of patients. Surviving children exhibit significant development delays in language and motor skills, along with various general cognitive impairments. Nearly 60–80% of surviving patients with the G406R TiS mutation meet the criteria for autism spectrum disorder while patients with the G402S mutation exhibit intellectual disability and developmental delay without autism (see section “[Evaluation and Differential Diagnosis](#)”). Seizures are experienced by 21% of patients with TiS.

Clinical Expression and Pathophysiology of Timothy Syndrome

Intellectual disability occurs in about 25% of individuals with TiS, though a number of other

cognitive impairments are also present. All adaptive functioning is impaired in TiS. Communication is significantly affected and language delay manifests early in development. Many children with TiS do not babble during infancy. Other language skills that are affected in TiS include articulation, reception, and expression. Other areas of adaptive functioning such as socialization, personal care, and daily living skills are impaired. The association between TiS and ASD is very high. Between 60% and 80% of patients with either TS1 or TS2 G406R mutations that survive the significant cardiac defects are diagnosed with ASD (Splawski et al. 2004). TiS is a syndromic autism spectrum disorder, an ASD with known genetic etiology that occurs in conjunction other specific phenotypes (Sztainberg and Zoghbi 2016).

TiS has attracted research interest because it arises from a known single amino acid mutation in a prominent signaling protein ($\text{Ca}_v1.2$) that generates ASD with high likelihood. Consistent with other lines of evidence for an important role of calcium channels in ASD (Lu et al. 2012), TiS provides a unique opportunity for pinpointing and dissecting mechanisms potentially involved in ASD. Building on the known genetics associated with TiS, investigations of altered neurological mechanisms have yielded valuable knowledge regarding activity-dependent neuronal signaling. Studies of TiS-associated mutations in animal models and induced pluripotent stem cells (iPSCs) have revealed important details about altered pathophysiological mechanisms underlying the disease (Bader et al. 2011; Bett et al. 2012; Krey et al. 2013). Both the G406R and G402S mutations result in excess calcium influx via the $\text{Ca}_v1.2$ channel upon neuronal depolarization (Splawski et al. 2005). This excess calcium influx is the result of altered channel inactivation (Barrett and Tsien 2008). Both mutations results in alterations in voltage-dependent activation. The G406R mutation exhibits a potentiating leftward 10 mV shift in the voltage-dependent activation of $\text{Ca}_v1.2$ (Splawski et al. 2005) while the G402S mutation exhibits a rightward shift. Additionally, the G406R mutation has be shown to exhibit

abnormal voltage-dependent conformational signaling (Li et al. 2016). Neurons expressing the G406R TiS mutation show excessive activation of activity-dependent genes specifically after increases in neuronal activity (Li et al. 2016). Both the G402S and G406R mutation confers defects in calcium-dependent inactivation and contributes to arrhythmogenesis (Dick et al. 2016). Furthermore, developmental studies have identified excessive activity-dependent retraction of dendrites (Krey et al. 2013) both of which are not associated with the increased calcium influx of $\text{Ca}_v1.2$ with a TiS mutation (Krey et al. 2013; Li et al. 2016), as well as aberrant migration and neurite formation during development in TiS animal models (Kamijo et al. 2018) and cultured human brain organoids (Birey et al. 2017). Genetic investigations in both human and animal models of TiS have revealed effects of the TS1 mutation on the alternative mRNA splicing of exon 8 and exon 8A (Panagiotakos et al. 2019). In addition to alterations in the electrophysiological functions of $\text{Ca}_v1.2$, the TS1 mutation confers altered exon 8A expression that results in continuous post-developmental expression of the pathological channel (Panagiotakos et al. 2019). Glial development and function are also affected by the TiS mutation. Myelinating oligodendrocytes possess increased calcium influx, mature at faster rates, and exhibit increased myelination during postnatal development. Animal models of TiS display readily discernable ASD-associated behaviors such as reduced socialization and increases in repetitive and perseverative behavior. The findings from these behavioral and mechanistic studies have important implications for broader questions about the underlying pathophysiological mechanisms in ASD (Bader et al. 2011; Mullins et al. 2016; Sztainberg and Zoghbi 2016).

Evaluation and Differential Diagnosis

Though TiS is characterized by many neurological and developmental features, it is typically suggested by the presence of cardiac QT

elongation accompanied by syndactyly and other facial deformities (Marks et al. 1995). Diagnosis can be suspect in a child before birth if fetal heart rates are found to be bradycardic. After birth, children with TiS can develop sudden hypoxia and present with cyanosis, a bluish discoloration of the skin. Subsequent cardiac evaluation of infants with TiS reveals 2:1 AV block as well as prolonged QT interval. However, there are forms of TiS where patients do not exhibit syndactyly. In order to properly diagnose TiS, single-strand conformational polymorphism sequence analysis or DNA sequencing of the CACNA1C gene is utilized (Splawski et al. 2004). It is important to identify TiS-associated mutations in the various exons of CACNA1C, as many of them are exclusively alternatively spliced (Tang et al. 2011). These mutations are gain-of-function mutations in the $\text{Ca}_v1.2$ L-type calcium channel. They are both genetically and phenotypically distinct from other heart-hand syndromes (HHS), such as Holt-Oram Syndrome (HOS). While patients with HOS generally present with congenital heart defects and upper-limb anomalies, they do not exhibit the QT interval elongation or cognitive impairments seen in TiS (Basson et al. 1994).

Treatment

TiS is a complex disorder that significantly affects multiple systems of the body. Its diverse phenotypic expression in various domains presents difficulties in targeting intervention and treatments for the many cardiac, neurological, immunologic, and other symptoms. Primary attention of treatment and intervention is placed on mitigating severity of life-threatening cardiac arrhythmias and associated heart defects. Despite the syndrome's rare nature, information regarding medical background and intervention is readily available from National Organization for Rare Disorders (NORD) and the Sudden Arrhythmia Death Syndromes Foundation (SADS).

The leading cause of death in patients with TiS is ventricular tachycardia and fibrillation. Because of its rarity, no significant data is

available regarding the effectiveness of numerous cardiac treatments. Beta-blockers have been suggested as a standard treatment for children with TiS. Whether beta-blockers are effective forms of treatment remains in question. Additional novel cardiac treatments such as sodium channel blockers have been proposed, with case studies describing their effectiveness (Gao et al. 2013). However, broad and long-term efficacy of these treatments remain in question. As the TiS-associated mutation occurs in L-type calcium channel, treatment with L-type calcium channel blockers have also been suggested. Studies in animal models have shown potential but have not been proven to be effective in humans with TiS. Other cardiac-specific interventions include the use of pacemakers and defibrillators concurrent with drug treatments for patients with TiS. However, immune systems of children with TiS are significantly affected. Consequently, any intervention utilizing internally placed devices poses a risk for infection. Additionally, anesthesia is known to trigger arrhythmias in TiS. Thus, any surgical intervention required to repair congenital cardiac defects will require extreme care by treating physicians and caretakers.

While the average age of death in TiS is 2.5–3 yrs., children have been known to survive into their teenage years. Neuropsychiatric evaluations of individuals with TiS reveals significant speech and developmental delays, intellectual disability, and autism spectrum disorder. Delays in development can be alleviated through a broad and integrated therapies such as social integration, speech, and physical therapies. Early intervention is key to show marked benefit in treating the numerous neuropsychiatric and cognitive symptoms of children with TiS.

Title IX

Ernst O. VanBergeijk
Vocational Independence Program, New York
Institute of Technology, Central Islip, NY, USA
Threshold Program, Lesley University,
Cambridge, MA, USA

Definition

Title IX is a federal civil rights law that prohibits any college or university that receives federal funding from discriminating against an individual upon the basis of their sex. This includes female, male, and

gender-nonconforming individuals. Recently it has been used to address sexual discrimination in a variety of forms including sexual harassment that involves both sexual violence and other forms of harassment not involving violence. Sexual violence includes but is not limited to sexual assault, rape, sexual battery, and sexual coercion. The goal of this legislation is to prevent these forms of violence from seriously limiting or even denying a student’s ability to participate or benefit from the school’s educational programs and activities. The law covers behaviors that occur both on and off campus.

According to the US Department of Education, the Office of Civil Rights (OCR) is responsible for the enforcement of Title IX as well as many other laws. The scope of Title IX according to OCR is the following:

Title IX applies to institutions that receive federal financial assistance from ED, including state and local educational agencies. These agencies include approximately 16,500 local school districts, 7,000 postsecondary institutions, as well as charter schools, for-profit schools, libraries, and museums. Also included are vocational rehabilitation agencies and education agencies of 50 states, the District of Columbia, and territories and possessions of the United States.

Educational programs and activities that receive ED funds must operate in a nondiscriminatory manner. Some key issue areas in which recipients have Title IX obligations are: recruitment, admissions, and counseling; financial assistance; athletics; sex-based harassment; treatment of pregnant and parenting students; discipline; single-sex education; and employment. Also, a recipient may not retaliate against any person for opposing an unlawful educational practice or policy, or made charges, testified or participated in any complaint action under Title IX. For a recipient to retaliate in any way is considered a violation of Title IX. The ED Title IX regulations (volume 34, Code of Federal Regulations, Part 106) provide additional information about the forms of discrimination prohibited by Title IX. (OCR [2015](#))

Historical Background

On June 23, 1972, President Richard Nixon signed Title IX of the Educational Amendments into law (U.S. Department of Justice [2015](#)). Initially Title IX was used in the 1970s to leverage equal opportunity for female athletes in university

sports programs (NCAA 2017). It was also used to protect pregnant students from being denied educational opportunities in both secondary and postsecondary institutions. This act amended the Higher Education Act of 1965, the Vocational Education Act of 1963, the General Education Provisions Act, and the Elementary and Secondary Education Act of 1965. The nickname of the Act is the Educational Amendments Act of 1972, rather than the longer title of all of the various acts it amended.

Current Knowledge

Recent media attention has highlighted the problem of sexual assault on college campuses. According to the National Sexual Violence Resource Center (2016), 1 in 5 women and 1 in 71 men will be raped in their lifetimes. College-aged students in general are at a much higher risk of sexual assault than other facets of the population. In fact, 11.2% of all students experience rape or sexual assault through physical force, violence, or incapacitation (among all graduate and undergraduate students) (RAINN 2016). According to RAINN, among undergraduate students, 23.1% of females and 5.4% of males experience rape or sexual assault through physical force, violence, or incapacitation (2016). A survey from the Association of American Universities (2015) confirmed the data with a finding that 23% of female college students experienced unwanted sexual contact. Well over 1/5 of transgender, gender-queer, and gender-nonconforming individuals have been sexually assaulted (RAINN 2016) which was also found to be the case in the AAU survey. The last finding is particularly important given the fact that recent research in the area of autism has found a higher incidence of gender nonconformity among ASD students. In a study conducted in the Netherlands, de Vries and her team (2010) found an incidence of 7.8% of the children, and adolescents in their sample had gender identity disorder. This prevalence is ten times greater than incidence that is found in the non-ASD population. Strang et al. (2014) found that participants with ASD in their study were 7.59

times more likely to express gender variance. There are approximately a ½ dozen studies that link autism and the expression of gender variance.

Clearly, students with ASDs, who have difficulty reading social situations and have difficulty self-advocating, are at higher risk of sexual assault than their nondisabled peers. They may be pressured into sexual behaviors or into drinking alcohol or recreational drug use. An individual cannot give consent to sexual activity if he or she is incapacitated due to drugs or alcohol. “A majority of all the victims of any nonconsensual sexual contact reported using alcohol or drugs prior to the incident: ranging from 61.7 percent to 93.8 percent,” in the 127 universities surveyed (Fisher et al. 2016, p. 39). “Victims of any nonconsensual sexual contact perceived that the offender was under the influence of alcohol or drugs prior to the incident (ranging from 66.7% to 83.8% across types of nonconsensual sexual contact)” (Fisher et al. 2016, p. 21).

Future Directions

Students on the autism spectrum need to understand that they must give affirmative consent for each and every sexual activity they are to engage in. This means they must agree to the sexual contact voluntarily and that the agreement is mutual. The agreement can be verbal or nonverbal. The nonverbal agreement is where students on the autism spectrum have the most difficulty. They may misunderstand or misread nonverbal cues. The consent should be given in a manner that both parties can understand. Consent must be given for each act and upon each occasion. What was okay between two parties on 1 day may not be okay upon another day. What can be even more confusing is that consent can be withdrawn at any time. Consequently, the sexual activity must stop immediately. The consent also must be given without any force, coercion, or intimidation. Silence is not consent. A lack of resistance, likewise, is not consent either. Future research should be aimed at how best to teach students on the spectrum of these complex social concepts.

In an effort to fit in, some students on the autism spectrum may be duped into saying or doing something to a fellow student that could be construed as sexual harassment. Nondisabled peers may goad a student on the spectrum into saying something about another student's anatomy, making a sexually suggestive comment or joke, or even kissing or groping another student. Students on the autism spectrum should read the university's student code of conduct in reference to the definitions of sexual harassment.

Most often male students on the spectrum may develop a romantic interest in a female student and not know how to express the interest in an appropriate manner. Here, the student on the autism spectrum should again consult the student code of conduct. Many times, these students are in violation of the student code of conduct in relation to the rules against stalking. These students find themselves facing disciplinary proceedings and not understanding why this is happening. High school transition programs should include social skills training in the areas of assertiveness, sexual harassment, and appropriate platonic and romantic relationships.

If you are a student on the autism spectrum or if you care for an individual on the spectrum and that person is a victim of sex-based discrimination, know that there are professionals at colleges and universities nationwide that are dedicated to helping students with this difficult situation. Look for your college's Title IX coordinator's name and contact information. He or she has a number of resources at her or his disposal to help you including counseling and health referrals, as well as support in filing reports and helping to insure your safety from further harm. It is imperative that a student receive help and support from family, friends, and health-care providers during this most difficult period. Future research needs to be aimed at preventing sexual assault among the ASD population attending college.

If you are a student on the autism spectrum who is accused of violating your college's code of conduct, know that the Title IX coordinator's job is to help support you through the process as well. He or she will inform you as to what exactly is going to happen, i.e., what the process will be,

what your rights are, what prohibitions you might face during the process, and finally what are the possible outcomes of the process. Tell the Title IX person the exact nature of your disability and what reasonable accommodations you might need, including designating a support person or advisor to you – who can help guide you through the process. Find out whether the college follows an investigator model or a judiciary or hearing model. An investigatory model may be easier for students on the spectrum to negotiate because it involves less people than a hearing panel model. Read your college's Title IX web page as well as the student code of conduct. Finally, future research should investigate how best to support victims of sexual assault who are on the autism spectrum, as well as individuals on the autism spectrum who are accused of stalking, sexual harassment, and sexual assault. A focus of this research should be what reasonable accommodations under the Americans with Disabilities Act would best help students with ASDs in these situations.

the 0–3 age group. Assessments for infants often include tests of neonatal reflexes and developmental motor milestones expected in the first year of life. Motor assessment for toddlers usually includes emerging use of writing and eating utensils, object manipulation, and play skills. This entry focuses specifically on the T.I.M.E. standardized assessment.

This test was designed to provide a comprehensive assessment of motor abilities, in conjunction with occupational and functional performance in children 4 months to 3½ years of age. It takes 10–20 min to administer to younger children and 20–40 min to administer to older children. The five primary subtests of the T.I.M.E. are mobility, stability, motor organization, social/emotional abilities, and functional performance.

Toddler Infant Motor Evaluation

Zoe Mailloux
Private Practice, Redondo Beach, CA, USA

Synonyms

TIME

Description

Toddler infant motor evaluation can be thought of as a generic term for assessment of various aspects of motor development and skills in babies and young children, although there is also a specific assessment known as the Toddler and Infant Motor Evaluation (T.I.M.E.). There are many developmental tests that include motor scales for

Historical Background

The T.I.M.E. was developed by Lucy Jane Miller, Ph.D., OTR, and Gale Roid, Ph.D., in 1994. It was designed to be a comprehensive assessment of motor development and quality of motor functions.

Psychometric Data

Standardization

Test items for the T.I.M.E. were developed following item generation and testing with a variety of ages and groups. The final test is standardized on a sample of 875 children (731 typically developing and the remainder children with motor delays or concerns). The normative sample is stratified based on the 1990 US census. The sample was divided into 10 age groups (0–12 months divided in 3-month intervals, 13–24 months in 4-month intervals, and 25–48 months in 6-month intervals).

Reliability

Internal consistency ranges from .72 to .97.

Test-retest – in a sample of 33 children (9% with motor delays) with a retest of 1–3 weeks, the test-retest correlation coefficient ranged from .965 to .998.

Interrater reliability – in a sample of 31 children tested by two independent examiners, the correlation coefficient ranged from .897 to .996.

Validity

Content validity was initially developed through expert analysis. Construct validity was established through age trends, factor analysis, and studies of dimensionality. Discriminant validity and classification accuracy were determined through a series of analyses, which demonstrated false positives between 1.1% and 11.8%, false negatives between 1.0% and 3.2%, specificity between 85.9% and 98.6%, and sensitivity between 80.6% and 97.2%.

Clinical Uses

The T.I.M.E. is conceptualized as a diagnostic assessment designed for use by a licensed or highly trained physical or occupational therapist, adaptive physical education teacher, or others with specialized training in the motor domain.

Definition

Humans exhibit plantigrade walking: They walk on the full soles (bottoms) of their feet. Toe walking involves walking on the balls (distal metatarsals/metatarsal heads) of the feet with the heel (calcaneus) raised up off the ground. Typically developing children will intermittently walk on their toes for a short while after first beginning ambulation. When the equinus gait is noticeably present after 3 months of walking, it is referred to as persistent toe walking. In the past, this was considered a sign of possible spastic cerebral palsy, but many children who toe walk do not exhibit any other signs of neuromotor disorder (hypertonicity, hyperreflexia, and upgoing Babinski reflexes). Orthopedics sometimes attributed this gait to a shortened tendo Achilles (short heel cord) even in the absence of a shortened ligament. Children with a neuromotor problem such as spastic diplegia will toe walk with their knees flexed, while children with idiopathic toe walking will toe walk with their knees extended. Since toe walking may be inhibited by certain types of shoes, its presence should be assessed with shoes off. Persistent toe walking has been noted to be more common in children across the entire spectrum of neurodevelopmental disorders apart from any motor diagnosis, and to be even more common in children with their language skills more severely impaired than the other developmental streams. Among children with language disorders, children with autism exhibit the highest persistence of toe walking, with close to 50% of 5-year-old children with autism continuing to exhibit at least an intermittent equinus gait (Accardo and Whitman 1989; Accardo et al. 1992; Shulman et al. 1997). The persistence of toe walking in children with autism may contribute to secondary motor deformity by producing a genuine shortening of the tendo Achilles. Treatments for this secondary deformity can include stretching exercises, casting or braces, Botox injections, and, in rare cases, heel cord lengthening surgery. Toe walking seems to be more correlated with the language component of autism, since it is not appreciably increased in children with Asperger Syndrome where language is less affected (Barrow et al. 2011). The etiology behind the

Toe Walking

Pasquale Accardo

Toilet Training

Kimberly Kroeger-Geoppinger
Cincinnati Children's Hospital Medical Center,
Cincinnati, OH, USA

Definition

The process of achieving continence by applying a systematic approach to teach another to gain control over urine and bowel movements. Successful toilet training is a combination of attaining continence while also completing the chain of behaviors associated with toileting including traveling to the

bathroom, undressing, voiding into the toilet, redressing, washing hands, and leaving the bathroom. Teaching continence in toilet training is often achieved using one or more of the following teaching components and strategies: scheduled sitting, urine alarms, reinforcement for in-toilet voids, hydration, prompting and prompt fading, over-correction, and environmental restitution.

Historical Background

The systematic teaching of toilet training was born in the 1960s paralleling the rise of behaviorism. Toilet training is one of the cardinal skills that lent itself to behavioral research in that it was relatively easy to study in terms of both target behavior descriptions and clear, definable outcomes. That is, voids were distinctly defined and mutually agreeable with little room for error in definition or observation. Similar to most of the behavioral research coming out of this era, the early work on toileting was conducted largely with institutionalized persons globally developmentally delayed or disabled, both children and adults, acting as samples of convenience. Early work focused on systematic presentation of prompts to void and positive reinforcement for accurate voiding behavior. The beginning body of toilet training research was furthered by Drs. Nathaniel Azrin and Richard Foxx who are credited with developing the rapid toilet training (RTT) method, the most cited and comprehensive toilet training protocol, and widely adapted for everyone from typically developing children to profound developmental disabilities such as autism to subspecialty, rare diagnoses such as Angelman syndrome. The novelty and appeal of the RTT approach was two-fold in that it provided a comprehensive approach targeting all toileting behaviors at once (i.e., bladder and bowel continence, as well as associated self-help skills of undressing and redressing) and achieved results in an extraordinary short amount of time (median of 4 days to train to independent toileting behavior). The original RTT method included hydrating the individuals for increased opportunity to void, using graduated guidance with prompt fading as

individuals were more successful with the set elimination schedule, contingency management with positive reinforcement for dry pants checked systematically and in-toilet voids and punishment consisting of overcorrection and environmental restitution for accidents and out-of-toilet voids. Despite the success of RTT, the protocol is often disaggregated and components used individually as training protocols in and of themselves. This reduction of protocol is largely due to shifts in treatment procedures and setting locations. Most notably, the use of punishment in primary treatment protocols has fallen by the wayside in support of more popular positive behavior support interventions and institutions have been replaced by home and school treatment settings, extending privacy rights with reduced apparatus needs.

Current Knowledge

The current state of the science for toilet training research supports the use of the Foxx and Azrin protocol, as well as its empirically supported derivatives. The RTT method has been largely adapted and widely accepted for its use in positive reinforcement protocols and as it applies to individuals with autism. Empirical evidence has repeatedly shown that an intensive toilet training method with positive reinforcement for target behaviors and void-specific contingency management is effective and, in turn, effective with children with autism. Most toileting studies published within the past 20 years focus largely on RTT-derived protocols and particularly in the area of positive reinforcement based training (see Kroeger and Sorensen-Burnworth 2009 for review; Kroeger and Sorensen-Burnworth 2010). Other areas of foci include stimulus controls studies and behavior-specific problem solving (e.g., Hagopian et al. 1993; Luiselli 1996). That is, the research has moved to cases where the established protocols have failed and revised the protocol to problem solve specifically at the target behavior. For example, if the individual only voids when in water, the intervention begins with first gaining control over the behavior in water. Non-academic professionals and paraprofessionals

also successfully implement the translational model of toilet training with a focus on the positive reinforcement contingent upon scheduled sittings. Often when the research becomes practice, residual issues are noted to occur including additional bowel movement training, communication to use the restroom, deficits in redressing, and non-self-initiated voiding.

Future Directions

Future research endeavors include expansion of trainer characteristics, as well as problem-solving residual issues. A number of toileting protocols exist within the literature, many of them successful and capable of generalization to a wide variety of individuals within the autism and developmental disability population. While most of the programs are modified versions of the toileting protocol presented by Foxx and Azrin, studies focus on abbreviating the protocols while also reducing steps, components, and professional training involvement. That is, the trend is to make less complicated the toileting protocols previously originated. Future areas of toileting literature should focus on the following: (1) collateral behaviors pivotal to successful toileting training, including communication, self-initiation, and bowel movement training; (2) exploration of age and functioning limits (i.e., how young to train and how cognitively disabled is trainable); and (3) review of necessary prerequisite skills suggested present before initiating toilet training. Such investigations will serve to continue the body of literature surrounding toilet training, while at the same time providing improved quality of life for individuals with autism spectrum disorders and intellectual disability.

Token Economy

Summer Ferreri
 Department of Counseling, Educational
 Psychology and Special Education, College of
 Education Michigan State University, East
 Lansing, MI, USA

Definition

The token economy is a highly individualized, reinforcement-based, behavior change system, derived from the principles of operant conditioning that can be used with individuals or groups. The specific components of a token economy include (a) the identification of measurable and observable target behaviors (e.g., verbal utterances, academic readiness behaviors) by intervention agents (e.g., teachers, parents), (b) the administering of tokens (e.g., points, check marks, real or imitation money), which function as generalized conditioned reinforcers, by the intervention agent to the participant, and (c) the exchange of tokens by the participant for a variety of backup reinforcers (e.g., line leader, computer time, snacks). Generally speaking, participants earn tokens contingent on the occurrence of target behaviors; subsequently participants exchange the tokens for a variety of backup reinforcers (Cooper et al. 2007). Likely the most widely known and

used token in the world is money. Money is not initially reinforcing but acquires the properties of a reinforcer after multiple pairings with another reinforcer; it is a conditioned reinforcer that can be exchanged for a wide variety of backup reinforcers (e.g., food, shelter, clothing, entertainment, transportation).

Historical Background

The origins of the token economy system can be traced back to Wolfe (1936) and Cowles (1937) during which time investigators provided tokens to chimpanzees when they engaged in correct responses, and later trained the chimpanzees to exchange the tokens for grapes. However, few token economy systems were utilized with humans prior to the 1960s. Pioneering research conducted by Ayllon and Azrin (1965, 1968) with adult psychiatric inpatients, as well as Staats and Wolf with children (Staats et al. 1962, 1964), resulted in the peak of token economy research with humans in the 1970s and 1980s.

The all-encompassing literature surrounding the token economy is beyond the scope of this entry (for a review of the literature see Kazdin 1982; Kazdin and Bootzin 1972; Matson and Boisjoli 2009; O'Leary and Drabman 1971); however, the contributions of the system are noteworthy and a brief mention of various previous research conducted on token economies including those outside of the autism literature demonstrate the robust nature of the system. The token economy has been shown to increase a variety of appropriate behaviors and decrease a plethora of inappropriate behaviors, in a wide array of settings, with diverse populations, such as spontaneous appropriate sentences in children with autism (Hung 1978), safety performance in open-pit mining (Fox et al. 1987), letter recognition and labeling with preschool children (Kincaid and Weisberg 1978), dietary compliance for children on hemodialysis (Magrab and Papadopoulou 1977), personal hygiene, personal management, ward work, and social skills with chronic psychiatric inpatients (Nelson and Cone 1979), school

achievement of children with Down's syndrome (Dalton et al. 1973), academic readiness behaviors of children with developmental disabilities (Playnick et al. 2010), academic performance of children with autism (Charlop-Christy and Haymes 1998), encouraging car pool formation on a university campus (Jacobs et al. 1982), cleaning and hygiene behaviors of maximum security correctional institution inmates (Milan and McKee 1976), and conversation skills for adolescents with autism (McGee et al. 1984).

The above paragraph is an indicator of the depth and breadth of token economy research and by the early 1970s there were sufficient studies conducted on the efficacy of token economies (although, not all specific to autism) (e.g., Birnbrauer et al. 1965; Broden et al. 1970; Bushell et al. 1968; Girardeau and Spradlin 1964; Hewett et al. 1969; Hunt et al. 1968; Hunt and Zimmerman 1969; Meichenbaum et al. 1968; O'Leary et al. 1969; Phillips 1968; Schaefer and Martin 1966; Tyler and Brown 1968) to warrant a comprehensive literature review. O'Leary and Drabman (1971) conducted a literature review of token economy systems in the classroom. The authors reviewed the literature, identified variables that could potentially influence token economy effectiveness, and provided an in-depth discussion regarding the concern that token economies did not necessarily result in generalization across situations or maintain upon withdrawal of the program. Additionally, Kazdin and Bootzin (1972) published an evaluative review of the token economy. This review of the token economy differed from that of O'Leary and Drabman in that it was not limited to the use of token economies in the classroom and it provided a discussion on the methodology of token economy investigations. However, there was one salient similarity between the reviews, and that was the lengthy discussion regarding stimulus and response generalization limitations and suggested procedures to increase generalization in future token economy investigations.

Early studies conducted with individuals with autism did not address generalization; however, they did demonstrate the efficacy of token

economy systems with individuals with autism on both basic and complex behaviors. Ferster and DeMyer (1961, 1962) taught individuals with autism a basic response (key pressing) through the use of tokens (i.e., coins), which could be inserted into a vending machine to obtain a variety of reinforcers (e.g., food). Metz (1965) extended the research by increasing the complexity of the target behavior. Metz reinforced nonverbal imitative responses of children with autism, with tokens, which could be exchanged for food. However, subsequent research may have been influenced by the suggestions provided by the O'Leary and Drabman (1971) and Kazdin and Bootzin (1972) reviews, as many studies specific to individuals with autism did attempt to assess the generalization and maintenance of behaviors learned during token economy interventions during the late 1970s and 1980s. Hung (1977) investigated the effect of token value manipulations on spontaneous question-asking and generalization. Results indicated that the occurrence of generalized spontaneous question-asking was minimal until token values were manipulated and increased. McGee et al. (1984) taught individuals with autism to make positive and negative assertions in the context of two game situations to increase conversational skills during leisure time with the use of a token economy system. Generalization from trained to spontaneous assertions did occur within response classes. A particularly impressive demonstration of generalization occurred in the investigation by Krantz, Zalsenski, Hall, Fenske, and McClannahan (1981) in which a token economy was used to teach individuals with autism complex expressive speech (i.e., the use of nouns, verbs, shapes/size, and color adjectives). Results indicated all children generalized their skills to a new teacher, a new classroom, and a new set of stimulus materials. Handen, Apolito, and Seltzer (1984) illustrated the assessment of maintenance. The authors used a token economy to decrease the rate of repetitive speech in an adolescent with autism and found that low rates of repetitive speech maintained at both a 9- and 14-month follow-up.

Kazdin (1982) published a follow-up paper to the Kazdin and Bootzin (1972) review that

discussed the significant issues related to effective token economy implementation such as staff training, client resistance, response maintenance, integrity of treatment, administrative and organizational issues, and dissemination of the token economy. However, the overall lack of current literature specific to the implementation of token economies with individuals with autism prohibits an analysis of research related to the issues raised by Kazdin nearly 30 years ago.

Current Knowledge

As previously stated, minimal research on the token economy related to individuals with autism is currently being conducted. In fact, Matson and Boisjoli (2009) conducted a review of the literature surrounding the token economy for children with intellectual disabilities and autism and found only seven investigations specifically related to individuals with autism (Handen et al. 1984; Hung 1977; Kahng et al. 2003; McDonald and Hemmes 2003; Odom et al. 1985; Steeves et al. 1970; Tarbox et al. 2006).

A majority of the studies conducted during this time frame fall into one of two categories. One, researchers were investigating the effects of the token economy as the independent variable on various dependent variables. For example, McDonald and Hemmes (2003) investigated the use of a token economy and prompts to increase social initiations by an adolescent with autism and reciprocity effects. Social initiations by the participant were higher during the token economy training conditions. Additionally, spontaneous staff initiations toward the youth increased during treatment when the frequency of the youth's initiations increased. Kahng et al. (2003) increased food acceptance in a preschool-aged child who had speech delay and possible pervasive developmental disorder by using escape from a meal and a token economy. The child could earn tokens by accepting a bite of food and she could exchange the tokens for meal termination. Results indicated that this condition (as compared to differential positive reinforcement of alternative behavior and differential positive reinforcement of

alternative behavior plus physical guidance) was effective at increasing the number of bites accepted and decreasing the instances of food refusal. Finally, Tarbox et al. (2006) used a token economy to increase the attending behavior of a young child with autism. Attending behaviors increased; however, the behaviors did not maintain during conditions in which the tokens were not exchanged for backup reinforcers and delay to exchange of the backup reinforcers occurred.

Two, investigators were interested in comparing various treatment approaches and the token economy is one component within the training conditions, that is not specifically being manipulated or assessed. For example, Gena, Couloura, and Kymissis (2005) conducted a comparison of video modeling and in vivo modeling to teach preschoolers affective behavior. However, both conditions included the use of verbal praise and a token economy. The authors reported that both treatments (in vivo and video modeling) successfully increased affective responding by all participants and generalization occurred across responses to untrained scenarios, the child's mother, new therapists, and time. Additionally, Hilton and Seal (2007) conducted a comparative analysis of applied behavior analysis (ABA) and Developmental, Individual Difference, Relationship-Based model (DIR) in twin brothers with autism. The ABA program, among other things, consisted of a token economy. The authors reported variable improvement in both the ABA and DIR programs.

However, there is a third category that includes research that has begun to investigate some of the salient issues raised by Kazdin's (1982) review. First, Kazdin iterated the importance of staff training and the relationship to procedural integrity within the constraints of existing settings, stating, "too little attention has been accorded the manner in which the program is monitored and implemented" (p. 437). Plavnick et al. (2010) assessed the effects of self-monitoring on the procedural integrity of token economy implementation by staff in a special education classroom. Additionally, the academic readiness behaviors (i.e., appropriate sitting and vocalizing) of students with autism and Williams syndrome were

assessed during conditions in which staff were (1) trained on token economy implementation, (2) independently implemented the token economy, and (3) self-monitored their implementation of the token economy. Results suggested that procedural integrity was high during the self-monitoring condition for the staff and the percentage of intervals in which students engaged in academic readiness behaviors increased during conditions of high procedural integrity. Second, Kazdin discussed the notion of client resistance to the token economy and subsequently suggested the creative selection of reinforcers and opportunities for clients to have input into the system. Charlop-Christy and Haymes (1998) investigated an important component of the token economy that involved creative tokens and participant input. The authors investigated the effectiveness of typical tokens (stars) and objects of obsession as tokens ("micromachine cards or trucks, the letter 'A,' names of characters from videos, and plastic beads") on task performance for children with autism. The participants performed with greater accuracy during the obsessions as tokens conditions, and although the authors provided many considerations for such results, it began to address the leading issues that Kazdin outlined many decades prior.

Based on the review of the literature above, it may be apparent that token economy systems vary greatly in terms of simplicity and complexity. The design and implementation of a token economy system can be cumbersome and requires meticulous planning and execution; however, if done properly, the system can be highly effective. Although future research is needed to address all the facets of token economy systems in relation to individuals with autism; the likelihood of implementing a successful token economy can be increased by utilizing the basic steps below:

1. Intervention agent identification.
 - (a) Determine who will administer tokens. Intervention agents may include one person (e.g., school professional, parent) or everyone employed in a school building (e.g., general educators, special educators,

- paraprofessional, bus drivers, administrators, cafeteria workers).
- (b) Administer detailed training to all individuals who have regular contact with the participant(s). Include procedures that specify the participants, target behaviors, tokens, rules regarding the distribution and exchange of tokens, identification of and availability of backup reinforcers, protocol for not meeting criteria, policies regarding unused tokens, plans for generalization, maintenance, and withdrawal of the token economy, and so forth.
 - (c) Monitor intervention agents.
 - (d) Evaluate and respond to the needs of the intervention agents.
2. Participant identification.
 - (a) Determine who will participate in the token economy. Participants may include, for example, just one individual, groups within a classroom, or all students within a school district.
 - (b) Determine criteria for the inclusion, exclusion, and removal of participants in the token economy.
 3. Target behavior identification. Myles, Moran, Ormsbee, & Downing (1992) provide the following guidelines regarding target behavior identification.
 - (a) Select observable and measureable target behaviors. These may be the same behaviors for all participants or different behaviors for each participant.
 - (b) Determine the criteria for each target behavior. For example, if "on-task" is the target behavior, how many seconds, minutes, or instances of on-task behavior need to occur before a token will be distributed.
 - (c) Require first a few, easy behaviors that gradually increase as the individual becomes successful.
 - (d) Ensure that the participant has prerequisite skills necessary to perform the target behavior.
 4. Token identification.
 - (a) Select tokens that are safe (cannot be swallowed or cause injury), unique (so that participants cannot buy, access, accumulate tokens independent of the occurrence of the target behavior), durable, readily available, and inexpensive (Cooper et al. 2007). The research is inconclusive regarding the comparative efficacy of neutral or highly desirable tokens (see Charlop-Christy and Haymes 1998 for one such investigation).
 - (b) Note that praise should always be paired with token distribution to increase the likelihood that praise will eventually function as a conditioned or generalized conditioned reinforcer.
 5. Backup reinforcer identification.
 - (a) Reinforcers should be nonintrusive and occur naturally in the environment (e.g., music, books, teacher helper) and should never prohibit the individual from accessing basic needs (e.g., food, warmth, hygiene products).
 - (b) If the above reinforcers prove to be ineffective, reinforcers that are not naturally occurring (e.g., candy, pop, video-game time) may be considered.
 - (c) Determine the price of the backup reinforcers. For example, highly preferred items may cost more than low preference items or items may be auctioned. Additionally, the cost of backup reinforcers may increase or the value of tokens may decrease as the participant becomes more proficient in the target behavior (Cooper et al. 2007).
 6. Cooper et al. (2007) suggest field-testing the system prior to implementation. Data from the field-test can be used to make adjustments to the system prior to full-scale implementation.
 7. Finally, participant training. Training procedures will vary based on the functioning level of the participant. For higher functioning participants, an explanation may suffice. However, lower functioning participants may require explicit training, models, physical and verbal prompts (Cooper et al. 1987). Snell (1983) offers a helpful step-by-step training protocol for training lower functioning individuals to use a token economy.

An optional element that can be used in conjunction with the reinforcement-based token economy is response cost. Response cost is a form of punishment by removal, in which reinforcement is removed based on the occurrence of inappropriate behavior and results in the decreased likelihood of such future behavior. For example, an individual with autism may earn tokens for the use of spontaneous communicative acts (e.g., unprompted exchange of picture symbols, unprompted vocal verbal mands, unprompted gestures) and lose points (i.e., response cost) for disruptive behaviors (e.g., humming, tongue clicking, aggression). Therefore, in a 30-min period, the individual may earn 10 tokens for spontaneous communicative acts, and lose 2 tokens for instances of aggression, in which case the individual would have 8 tokens available for exchange of backup reinforcers. There are many serious considerations that should be contemplated before deciding upon the use of any punishment-based system, and response cost is not an exception. For more information regarding these considerations, please see Cooper et al. (1987, 2007).

Future Directions

The future direction of token economy research specific to individuals with autism is largely unknown. Historically, there was a flurry of research during the 1970s and 1980s, but has nearly ceased in recent decades. There are still many unanswered questions regarding token economy systems and individuals with autism. For example, it would be important to, (a) consider the feasibility of training intervention agents such as parents, teachers, caregivers, speech and language pathologists, or individuals other than researchers, (b) assess the effects of procedural integrity on participant skill acquisition, (c) identify the ideal schedules of reinforcement to maintain performance upon the removal of token economies, (d) study the effects of participant input on reinforcer and contingency selection, (e) address all aspects of stimulus and response generalization, (f) study efficacy of token economies in relation to participant demographics, such as age, cognitive

level, and specific diagnosis on the spectrum, (g) compare individual versus group token economies, and (h) compare the token economy to other treatment options in terms of time, cost, resources, feasibility, utility, social validity, and efficacy. However, ultimately the future direction of autism research as it relates to the token economy will be determined by the research questions that investigators deem most crucial, applicable, and feasible at that point in time. The possibilities are endless and the future is quite exciting.

Token Test for Children – Second Edition (TTFC-2)

Marta Martinez, Mariah Eykelhoff and Rachael Quicquaro
Southern Connecticut State University, New Haven, CT, USA

Synonyms

TTFC-2

Description

The *Token Test for Children, Second Edition* (TTFC-2) is a quick 10- to 15-min screening

measure intended for identifying receptive language difficulties in children ages 3–12 years and 11 months. The overall score reflects the child’s ability to follow multiple-step oral directions, understand spoken language components, and recall short-term auditory memory. Syntactic structures, knowledge of prepositional and relational concepts, and semantic development are among the linguistic components assessed. The TTFC-2 manual notes that the test is an effective addition to comprehensive language assessment as a means of gathering targeted information of receptive language skills. Results from the TTFC-2 provide specified information that allows clinicians to glean the relative impact of receptive language difficulties and “subtle language deficits” on functional language and communication outcomes (Harris et al. 1983). Harris et al.’s (1983) exploration reveals that there is a parallel relationship between dichotic listening tasks and TTFC results, wherein results on the TTFC aligned with higher deficits in dichotic listening. Thus, the TTFC provides an accurate indicator of receptive language abilities that can be used when investigating relationships among receptive language abilities and other auditory language tasks. In this way, the TTFC-2 is a useful measure that provides critical information about receptive language deficits as a variable in overall language outcomes.

The TTFC-2 manual highlights that some training is necessary in order to ensure that internal consistency measures are accurate. Thus, the TTFC-2 may be administered by speech-language pathologists, school psychologists, special education teachers, education specialists, and those with training in standardized test administration (DiSimoni et al. 2007). Administration protocol begins with three unscored practice items before the evaluation. The test consists of 46 verbally transmitted commands that are divided into 4 parts according to level of complexity. The clinician is required to administer all 46 test items in *successive* order given the exception of children who cannot successfully complete the practice items.

Following the test administrator’s command, the test-taker is required to manipulate the

provided tokens under the constraints of the command. Commands are varied in length and complexity and utilize the variety of token colors and shapes to add complexity to each portion of the test. The materials required for administration include the TTFC-2 manual, 20 token manipulatives that differ in size (small and large), shape (circle and square) and color (green, blue, red, yellow, and white), and the provided test sheets (Alkhamra and Al-Jazi, 2016). The data recorded on the test sheets provides a measurement of test-taker success as a function of their ability or inability to successfully complete the verbal commands. Thus, score interpretation of the TTFC-2 identifies children that are significantly below their peers in receptive language abilities.

Five distinct types of informative scores, namely, standard score, percentile rank, standard error of measurement (SEM), descriptive rating, and listening age, are obtained from the recorded raw score. The standard score, age equivalents, and percentile ranks are converted from the raw score, and the SEM is a measure of age and coefficient alpha. As a final measure, six descriptive ratings ranging from very poor to very superior are obtained from the percentile ranks and standard scores (DiSimoni et al. 2007).

The scores on the TTFC-2 are a measure of language comprehension through the receptive mode. All scoring for the TTFC-2 is scored as correct (1) or incorrect (0). To receive a correct score, the task must be performed with 100% accuracy; no partial credit is received. Distractibility, impulsiveness, as well as a severe physical disability should be considered as possible confounding factors that may account for depressed scores (DiSimoni et al. 2007). Thus, lower scores on the TTFC-2 resulting from the inability to successfully carry out the commands may indicate the presence of a developmental disorder or extreme impairment of visual processing ability.

Historical Background

The original *Token Test*, designed by DeRenzi and Vignolo (1962), sought to measure receptive

language comprehension in adults with aphasia by way of following directions applied to token manipulatives. Several adaptations were made following the earliest rendition, all of which measured the patient's ability to manipulate the tokens upon five sets of oral commands that systematically increased in both length and complexity.

The emergence of research by DiSimoni in 1978 questioned the *Token Test's* efficacy when evaluating children for several reasons, including lack of age norms, socioeconomic group comparisons, and lack of clarity in data collection. This research prompted DiSimoni's development of the *Token Test for Children* (TTFC) in 1978, which integrated the variety of command sequences and use of tokens present in the original test with standardized administration protocol and increased sample size to forge its viability for children aged 3 years to 12 years and 6 months.

Following the development of the TTFC, later research suggested that despite improvements in standardization and clarity, deficits in the psychometric stability of the test remained present. In 2007, DiSimoni, Ehrler, and McGhee developed the second edition, the TTFC-2, with detail to improving validity, reliability, and normative data to be critically representative of the demographics of the current US population. The TTFC-2 aims to improve shortcomings by providing targeted performance data based on a variety of ethnic, gender, disability, and race discrepancies.

Psychometric Data

Standardization data represents the total population by matching sample criterion to the overall geographic region, gender, race, and exceptionality data noted in the US Census data report in 2004–2005. The standardization population consisted of 1310 children from 22 states and 136 geographically diverse communities. Various exceptionalities were presented in the inclusion of children with specific language impairment (SLI). The normative sample mirrors the current population, where 7% of the normative sample were children with SLI and 7.42% of the total

population is constituted by those with SLI (DiSimoni et al. 2007).

The representation of the sample spans across three targeted subgroups. These subgroups consist of children who were classified as representative of the mainstream, minority, or exceptional population. The mainstream subgroup includes male and female Caucasians while the minority subgroup includes male and female African Americans, Hispanic Americans, Asian Americans, and American Indians. Finally, the exceptionality subgroup includes those children who are gifted and talented as well as individuals with autism, attention-deficit/hyperactivity disorders, articulation disorders, intellectual disabilities, learning disabilities, or SLI (DiSimoni et al. 2007).

The test reliability, validity, and score comparison results indicate consistencies and demonstrate the efficacy of the battery. Reliability is substantially positive with coefficients that range from an average of 0.96 for test-retest reliability to 0.99 for interscorer reliability. Validity coefficients further evidence consistencies through construct-identification and criterion-prediction validity that both indicated validity as a measure of five testable questions and three independent studies. Evidence of validity is further propagated by conventional and differential item analysis techniques that revealed accuracy in capturing the variance of receptive language skills as well as a lack of bias in the language of the command stimuli. As a final measure of validity, the scores and measurements from the TTFC-2 were directly compared with the Test of Early Language Development (TELD-3), the Receptive One-Word Picture Vocabulary Test (ROWPVT-2000), and the Expressive One-Word Picture Vocabulary Test (EOWPVT-2000) to reveal significant correlations with coefficients at the 0.001 level. Thus, the reliability and validity measures support the efficacy and psychometric stability of the TTFC-2 (DiSimoni et al. 2007).

Clinical Uses

The literature reveals that the TTFC-2 is not only a useful tool for children who speak Standard

American English, but also holds clinical utility when serving several diverse cultural-linguistic communities. Research by Alkhamra and Al-Jazi (2016) unveil the Arabic Token Test for Children (A-TTFC) as a valid, reliable, and appropriate measure of receptive language in the assessment of children who are native speakers of Arabic. The A-TTFC was developed as a translation of the TTFC, and as a translated test, the “content of the test and the construct measures most likely do not change. . .the test score is therefore less threatened” (Alkhamra and Al-Jazi 2016, p. 184). The study investigates this probability by systematically evaluating the performance of 397 Jordanian children on the A-TTFC. Prior to their evaluation, each child was tested to ensure their ability to hear the linguistic commands via administration of the Ling Six Sound Test. Data collection to determine the efficacy in standardization of the A-TTFC was performed through factor analysis, bilingual validation, and age difference analysis in order to “support the accuracy of the translation process [as well as] the validity of the A-TTFC” (Alkhamra and Al-Jazi 2016, p. 189). Thus, the A-TTFC provides a formal tool for receptive language assessment in native Arabic-speaking children that maintains the same clinical strengths and utility as the TTFC-2 for native English speakers.

In addition to the A-TTFC, research by Gallardo et al. (2011) uncovers many available versions of the TTFC that have been developed in Dutch, German, Khmer, Kannada, Polish, Portuguese, and several Spanish-speaking populations. Yet, the authors posit that many of these versions may not be viable for use in practice, as there is a lack of standardization and psychometric evidence that is necessary for efficacy (Gallardo et al. 2011). Thus, Gallardo et al.’s study sought to explore these measures of efficacy in the Revised Token Test (RTT) in 250 Spanish-speaking children aged 4–12 years old. Analyses of vocabulary knowledge and intelligence were recorded as a means of obtaining language performance overall before administering the tests. The RTT results were then correlated with the results on the prerequisite testing in order to determine criterion validity. Additional measures of factorial analysis and analysis of variance were carried out to arrive at a statistical

outcome. Results from this study indicate that the RTT is a reliable and valuable tool for the assessment of Spanish-speaking children due to its psychometric sensitivity. While the authors outlined these positive outcomes, they caution clinicians that further research into the normative data and increased sample size is warranted prior to use of the RTT with Spanish-speaking children (Gallardo et al. 2011).

Department of Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, USA

Synonyms

[Topiramate](#)

Definition

Topamax is an anticonvulsant. The drug works by inhibiting glutamate activity (major excitatory neurotransmitter), attenuating activity of Na⁺ channels and high-voltage-activated Ca²⁺ channels (preventing depolarization, i.e., excitation),

and further potentiating gamma-aminobutyric acid (GABA) receptor-mediated inhibitory cell signaling. While there is some evidence of its effectiveness in ASD, further validation is required. Topamax's mechanism of action is in concordance with theories of increased excitation in ASD patients. Side effects may include weight loss, somnolence, and anorexia.

Total Communication (TC) Approach

Vannesa T. Mueller

Speech-Language Pathology Program, University of Texas at El Paso College of Health Science, El Paso, TX, USA

Definition

Total communication (TC) is an educational philosophy which was introduced to the field of deaf education in the 1960s (Schow and Nerbonne 2007). TC utilizes all modalities of communication (spoken, signed, and written) as well as lipreading, and gestures in the education of deaf children. Simultaneous communication (SimCom) is typically used in education settings that boast a TC approach (Power et al. 2008). Users of SimCom speak and sign simultaneously. Because American Sign Language (ASL) uses a different grammar and syntax from English, out of necessity the sign system that is used during SimCom is some form of manually coded English or a form of pidgin sign language. Because other forms of communication are used with children with autism, the total communication approach includes not only speech, signing, gestures, and written language, but also picture communication and voice output communication devices.

T

Historical Background

TC has been used in some form since the beginning of deaf education in the sixteenth century (Evans 1982). It was not until the mid-1800s that an oral-only approach began to take hold of the field of deaf education. In 1880, deaf educators from Europe and the United States met at the International Congress at Milan to discuss the

then-current debate over which educational philosophy (oral-only or a sign and spoken combined method) should be used. The results of the Congress at Milan led to a predominately oral-only approach in European countries and in the United States. The purely oral-only approach dominated the field of deaf education until the 1960s when David Denton at the Maryland School for the Deaf developed the idea for the TC approach (Lowenbraun et al. 1980).

In the 1960s, many researchers and educators of the deaf began to question the oral-only methods of teaching due to the alarmingly high numbers of illiterate or barely literate deaf students (Boatner 1965; Schein and Bushnag 1962; Trybus and Kachmer 1977). Also available at the time was research that focused on the comparisons of deaf children of hearing parents and deaf children of deaf parents. It was found that deaf children of deaf parents outperformed deaf children of hearing parents in measures of academic achievement and literacy skills (Quigley 1969; Stevenson 1964). These differences were attributed to the use of American Sign Language among the deaf families.

Both then and now, the total communication approach is not implemented homogenously. Stuckless (1976) was the first to point out that total communication “means different things to different people.” The inclusion of finger spelling to a largely oral-only approach is enough to label some programs TC. On the opposite end of the spectrum, programs that are based primarily on American Sign Language as the language of instruction and include written English label the educational philosophy TC. The following definition of TC was provided in 1976, and it remains the same today. TC is a “philosophy incorporating the appropriate aural, manual, and oral modes of communication in order to ensure effective communication with and among hearing impaired persons” (Garretson 1976, p. 300).

Although not labeled “total communication,” the approach was first used with children with autism in the 1970s. Carr et al. (1978) were among the first to use sign language with children with ASDs. The use of signs for nonverbal children with ASDs is still employed widely today. In

addition to the use of signs, picture symbols, picture communication boards, and low-tech and high-tech augmentative and alternative communication (AAC) devices are used with children with ASDs, and the approach is also termed “total communication” because any form or modality of communication is applied.

Rationale or Underlying Theory

The rationale for the TC approach has its beginnings in deaf education. In the 1960s, the attention turned to manual approaches of communication and education due to research that showed a more favorable outcome in literacy skills for children who were either born to deaf parents or who were educated through sign language (Hester 1963; Meadow 1968; Quigley 1969). This finding has been echoed in the literature more recently (Hermans et al. 2008; Strong and Prinz 2000). The basic findings correlate signing ability and reading ability such that those with better signing skills are better readers. It makes sense that those children who are better signers would be in an environment with much sign exposure such as in a household with deaf parents who use ASL.

Related to this is a proposal first described by Cummins in 1979 called the linguistic interdependence theory. The theory was originally meant to suggest an adjustment to bilingual education in a way that would incorporate the basic tenets of the model. Cummins (1979) asserts that the competence that can be achieved in a second language (L2) is dependent on and restricted by the competence individuals have in their first language (L1). Additionally, children must reach a threshold competency level in their L1 before learning an L2 becomes too cognitively taxing. Although the linguistic interdependence theory was not meant to be applied to deaf children, many see a parallel between the obstacles deaf children face when learning written English and the obstacles a second-language learner faces. Indeed, if a child learns ASL, which is a separate language from English, learning written and spoken English is an issue of a bilingual learner.

Regarding individuals with ASDs, the TC approach has been applied due to research that began in the 1970s related to the speech outcomes of children with autism who were taught manual signs. More recently, related to the idea of multiple intelligences (Gardner 1993) is the notion that, much like the normally developing population, individuals with ASDs are a heterogeneous group with different strengths and learning styles. Specifically, it has been found that some individuals with ASDs have differences in the way they process information (Harris et al. 1990; Siegel et al. 1996). Hermelin and O’Conner (1970) were the first to state that some individuals with ASDs process visuospatial information better than auditory information. Additionally, it has been found that the memory of individuals with ASDs is superior for visual information compared to auditory information (Prior and Chen 1976). Finally, research on the attention of individuals with ASDs supports the notion that they have difficulty selecting the most salient features of a stimulus (Frith and Baron-Cohen 1987).

The use of other forms of augmentative communication for individuals with ASDs seems logical based on the strengths that they possess. The use of sign language relieves the burden of having to process verbal information and builds on the strength of processing visuospatial information. The memory difficulties of individuals with ASDs can be alleviated by using picture communication symbols which do not require them to rely on their own memories to create a message. Individuals with ASDs can attend to the symbols for as long as necessary to comprehend the information, alleviating the difficulties related to attention needed for verbal information transfer. Sign language is seen as a viable option for nonverbal individuals with ASDs due to the ease with which the therapist can physically manipulate the hands for manual articulation compared to manipulating the mouth during speech production.

Goals and Objectives

It is estimated that 30–50% of individuals with autism spectrum disorders will not acquire

functional speech (National Research Council 2001; Luyster et al. 2005); the goal of the total communication approach is functional communication. Although verbal speech may not be possible for all individuals with autism, communication through any means is the ultimate goal.

Treatment Participants

Any individual who is unable to communicate to the level expected for their age is a candidate for augmentative and alternative communication of any form (Beukelman and Mirenda 2005). Therefore, because communication impairments are a hallmark of ASDs (Mirenda 2009), many individuals with ASDs are candidates for a total communication approach.

Treatment Procedures

Because the total communication approach is an eclectic one, there is no one set of procedures to be applied. Typically, whether referring to the use of manual signs or picture communication, the common practice is to begin training a small number of lexical items for requesting highly motivating objects (Beukelman and Mirenda 2005). Once the use of symbolic communication is established, more lexical items are introduced and are used for other communicative acts such as commenting and questioning.

Beukelman and Mirenda (2005) also support the use of natural consequences when applying AAC solutions to beginning communicators. For example, when using picture symbols to request an item, the language facilitator should provide the item that is requested even if the facilitator knows the request was a mistake or knows that the AAC user does not want the item. Giving the non-preferred item, and allowing for the natural consequence, teaches the AAC user that they must pay attention to their own communicative interactions and that they must weight their options carefully.

Efficacy Information

Efficacy research in the field of AAC is a relatively new addition to the literature. Bedrosian (1999) states that much early research in the field, as it should have been, was devoted to descriptive studies relating to describing the communication of AAC users. Since that publication, many more research studies have been conducted that are devoted to the efficacy of AAC for specific populations. Autism is one of those populations that have been widely studied. Overwhelmingly, the use of AAC has resulted in increased language skills in individuals with ASDs over treatment approaches that focus on speech alone. For most individuals with ASDs, accessing their relative strength in the visual domain has resulted in faster and more complex language growth in both signing and speaking. The use of manual signing in combination with speech training has been shown to increase language skill. The use of non-electronic-aided systems such as picture use has also been shown to increase functional communication, and a wide range of individuals with ASDs have been able to make use of this type of communication. High-tech AAC use has been shown to increase language abilities and speech output in individuals with autism as well. See Goldstein (2002) and Mirenda (2002) for reviews.

A meta-analysis of available research related to AAC use was conducted by Millar et al. (2006). Although the meta-analysis was not focused only on individuals with autism, the major finding was that use of AAC does “not have a negative impact on speech production” (p. 257), and in fact, speech production increased in individuals ages 2–60 years as a result of AAC interventions and across a range of different AAC interventions (aided and unaided).

Outcome Measurement

Because the goal of AAC use is functional communication, the outcome measurement should be the same. Functional communication will be defined differently based on the

cognitive skills of the individual and the type of AAC system that is in place.

Qualifications of Treatment Providers

AAC interventions are most typically introduced by a speech-language pathologist. Unfortunately, many speech-language pathologists do not report having adequate training or education in the field of AAC (King 1998; Marvin et al. 2003; Simpson et al. 1999), and a survey of education programs for speech-language pathologists has uncovered a need for better education in this area (Ratcliff et al. 2008). Although this is the case, speech-language pathologists are the best equipped of all professionals who work with individuals with autism to provide intervention that includes AAC. A listing of speech-language pathologists who are certified by the American Speech Language Hearing Association can be found on their website. A few short questions posed to the speech-language pathologist can reveal whether they are comfortable with the area of AAC.

Touch

► Tactile

Touch Pressure

Winifred Schultz-Krohn

Department of Occupational Therapy, San José State University, San José, CA, USA

Definition

Touch pressure is a specific form of touch sensation, recording the amount of push on the receptor with the ultimate goal to avoid skin damage. The sensation of touch pressure is detected by skin receptors designed to provide graded information to the brain through spinal cord pathways. This touch pressure can be noticed, but if not perceived to be a threat to the integrity of the skin, then no action is taken. Occasionally, the term touch pressure is used to refer to the use of therapeutic touch in the form of massage or touch therapy to calm children who are diagnosed with autism.

Definition

Deficits in sensory functioning were recently recognized under the repetitive behavior criteria for the diagnosis of autism spectrum disorder (ASD) (APA 2013). It is estimated that atypical responses to sensory stimuli are present in 90% of individuals diagnosed with ASD (Tavassoli et al. 2014; Tomchek and Dunn 2007), with the sense of touch described by parents as one of the most impaired (Hilton et al. 2010; Lane et al. 2010).

Touch is a sensory modality used in the context of affiliative behaviors and social interaction, and some have proposed that it precedes more complex forms of social-emotional skill development, such as language or emotional expressiveness (Hertenstein et al. 2006). Touch is important to human social bonding and affect communication because it is a primary channel of communication in the first year of life (Gallace and Spence 2010; Morrison et al. 2010). ASD is a disorder characterized by a lack of social-emotional reciprocity, and a relationship between the tactile domain and other core symptoms of the disorder, namely, social problems, has been suggested. Specifically, it is hypothesized that aberrant touch processing is a potential precursor to these deficits.

Abnormal touch processing in ASD is often characterized by abnormal responses to textures, preoccupations with sensory features of objects, or problems habituating to prior sensory experiences (Hilton et al. 2010; Lane et al. 2010). Other

reports include defensive reactions and lower pleasantness ratings to tactile stimuli (Tomchek and Dunn 2007). Abnormal responses to touch in ASD seem to be present, prodromally, in the first year of life (Kadlaskar et al. 2019). Specifically, infants who are later diagnosed with ASD fail to shift their attention in response to caregiver touch, and even when they do attend to their mother's touch, they seem to orient away from it. In addition, infants who attend less to caregiver's touch at 12 months old present more ASD symptomatology as measured by the autistic diagnostic observation tool (ADOS) at age 3 (Kadlaskar et al. 2019). There seems to be evidence of tactile disfunction early in ASD, but the abnormal responses are heterogeneous and may have different etiologies.

Missing tactile stimuli in the environment (sensory hyporesponsiveness) has been found previously in young children with ASD (Foss-Feig et al. 2012). However, there are other mechanisms by which sensory impairments may relate to symptoms of ASD. For example, the degree to which a child seeks (sensory seeking) or is bothered by tactile stimuli (sensory hyperresponsiveness) can also result in failing to attend to appropriate stimuli in the environment and consequently result in missed learning opportunities (Baranek et al. 2007).

Atypical behavioral responses to touch may directly impact the way children and adolescents interact with others, both contemporaneously, and over time. It is hypothesized that children engaging in sensory seeking behaviors are too distracted with enhancing their sensory experiences and therefore miss social cues in their environment (Foss-Feig et al. 2012). Others suggest that hyperresponsiveness/tactile defensiveness is the pattern that mostly affects the ability to socialize in ASD (Miguel et al. 2017) and is in fact one of the patterns of behavior that best differentiates ASD from typically developing children. However, hyporesponsiveness to touch seems to be the pattern that gathers greater consensus among researchers on the cascading effects on development over time (Foss-Feig et al. 2012; Miguel et al. 2017). Children who miss tactile experiences due to hyporesponsiveness will have fewer opportunities to engage meaningfully and learn from their physical environment and social experiences.

The relationship between tactile and social processing in ASD may occur at multiple levels, and it is not yet well understood where in the biological hierarchy (e.g., sensory receptors, perception, attention, cognition) there is a breakdown that results in ASD behavioral characteristics (phenotype). Some studies point to differences in how tactile stimuli are processed at a peripheral level, namely, touch detection and stimuli discrimination, but findings are inconclusive (Riquelme et al. 2016). Others suggest differences in neurotransmitters – specifically GABAergic function (the major inhibitory neurotransmitter in the central nervous system), crucial for balance between excitatory and inhibitory tactile input at a cortical level (Tavassoli et al. 2016). A specific class of tactile mechanoreceptors, C-tactile (CT) neurons, involved in encoding the valence/pleasantness of a stimulus (Loken et al. 2009), have been hypothesized to underlie the atypical responses in ASD. By encoding the valence of a stimulus, these fibers are intrinsically related to social cognition and our ability to bond with others. Children with ASD present more aversive reactions to touch delivered to CT-innervated body regions, such as the face and arm, compared to non-CT-innervated regions, such as the palm of the hand (Cascio et al. 2016). Moreover, at a brain level, children with ASD show diminished responses in social-affective brain networks compared to typically developing children following CT-targeted touch stimulation (Kaiser et al. 2016).

Touch processing seems to be altered in ASD; however, how heterogeneous behavioral responses to touch are related to social-communication problems in ASD is under deliberation. Atypical touch processing, whether characterized as hyporesponsiveness, sensory seeking, or hyperresponsiveness, can result in reduced exposure to important stimuli causing an altered trajectory of the developing social brain in infancy. Altered tactile processing emerges before many of the social and communicative impairments associated with ASD and has strong theoretical grounding as a developmental precursor to social-communicative behavior. By understanding the behaviors and mechanisms that underlie atypical touch processing, we can design and improve diagnostic and treatment tools for these individuals.

Touch Sensitivity

M. Kristen
Center for Children with Special Needs,
Glastonbury, CT, USA

Synonyms

Sensory integration and praxis tests (SIPT);
Sensory processing; Tactile sensitivity

Definition

Touch sensitivity, or sensitivity to tactile stimuli, has been noted in children with autism spectrum disorders (Baranek et al. 1997). Children with tactile hypersensitivity may show a reluctance to manipulate various toys, materials, or foods based on their texture or may exhibit exaggerated or persistent responses to unexpected touch occurrences and may even avoid situations in which these events or unusual textures may occur. Some children may be hypervigilant to the potential threat of unexpected touch which may ultimately compromise successful participation in a designated activity. Clothing selection, play materials, and food choices may also be restricted if they are perceived to be unpleasant to the individual. Some individuals may exhibit hyposensitivity to touch or an underreaction to touch occurrences. These individuals may display a more passive response to tactile stimuli and may not notice when clothing is twisted on their body or food is left on their face. Tool usage may also be affected as the individual may not have adequate feedback in the hand for effective manipulation.

Tourette Disorder

► [Tourette Syndrome](#)

Tourette Syndrome

Michael Bloch

Yale OCD Research Clinic, New Haven, CT, USA

Synonyms

[Gilles de la Tourette syndrome](#); [Tourette disorder](#); [Tourette's syndrome](#)

Short Description or Definition

Tourette syndrome is a childhood-onset neuropsychiatric disorder characterized by multiple motor and vocal tics that occur for at least a year in duration.

Categorization

Tic Disorder

Epidemiology

Transient tics, which have a duration of less than 6 months, are common in childhood. Estimates suggest that 4–24% of school-aged children experience tics (Khalifa and von Knorring 2003; Scahill et al. 2005). Roughly one-quarter of children experience chronic motor or vocal tics. Chronic tics have a duration of at least 1 year. Once thought to be much rarer, the current

lifetime prevalence estimates for Tourette syndrome ranges from 0.1% to 1%. Tic disorders are much more common in children with pervasive developmental disorders and in special education populations than would be expected by chance (Canitano and Vivanti 2007; Kurlan et al. 2001). Studies have estimated that the occurrence of Tourette syndrome may be greater than 10% among autistic children (Canitano and Vivanti 2007).
